THE REFRACTION OF THE EYE

By the same Author

THE OPHTHALMOSCOPE: A Manual for Students. Third Edition, with 4 coloured plates and 68 woodcuts.

PHILLIPS. Spectacles and Eyeglasses. Their Prescription Forms, Mounting, and Proper Adjustment. By R. J. PHILLIPS, M.D., Adjunct Professor of Diseases of the Eye, Philadelphia Polyclinic; Ophthalmic Surgeon, Presbyterian Hospital. Second Edition, Revised and Enlarged. 49 Illustrations. Cloth, net, $1.00

The proper frame to be used and its correct adjustment are quite as important as the writing of the prescription for the glass; an unskilled mechanic will nullify the scientific work of the physician. The object of the book is to supply the latest and best knowledge upon a neglected subject, to inform the physician about matters that will promote the best result of his efforts to correct faults of vision, and to help the manufacturer to meet the scientific requirements so essential to present demands.

From The Medical Record, New York.

"The book is issued as an aid to those who prescribe and who sell eyeglasses and spectacles, for the purpose of enabling them to reach the most satisfactory and beneficial results in the adjustment of lenses to the eyes of patients. Since the proper adjustment of spectacles and eyeglasses is of very great importance, it is desirable that the rules and suggestions contained in this little volume should be familiar to every oculist and optician."

GOULD AND PYLE. Compend of Diseases of the Eye and Refraction. Including Treatment and Operations, with a Section on Local Therapeutics. By GEORGE M. GOULD, M.D., Author of Gould's Medical Dictionaries; Editor *Philadelphia Medical Journal;* and W. L. PYLE, M.D. With Formulæ, Glossary, and several Tables. 111 Illustrations, several of which are Colored. Cloth, net, .80

From The Annals of Ophthalmology.

"The most comprehensive treatise for students and general practitioners in ophthalmic literature."

*** A Special Catalogue of Books on Diseases of the Eye and Refraction will be sent free upon application.

PREFACE

TO THE

TENTH EDITION.

In preparing the tenth edition of 'Refraction of the Eye' for publication, the original plan of the book has been maintained, and no effort has been spared to make the work more worthy of the favour with which it has been received in this country and abroad.

Although but a short time has elapsed since the last large edition was brought out, every page has been carefully revised, and alterations made in accordance with our increasing knowledge of the subject.

March, 1900.

PREFACE

TO THE

FIRST EDITION.

I HAVE endeavoured in the following pages to state briefly and clearly the main facts with which practitioners and students should be acquainted, in order to enable them to diagnose errors of refraction accurately, and to prescribe suitable glasses for their correction.

Those who would do this with facility can only acquire the requisite amount of dexterity by practically working out a large number of cases of refraction. No book, or even the knowledge gained by watching others who are thus employed, can take the place of this, the practical part of the subject.

To many of my readers the chapter on Optics may appear unnecessary. I have added it for the benefit of those whose school education did not include this subject, since its elementary details so completely underlie the whole subject of refraction, that every

student should understand them thoroughly before passing on to the real subject in hand.

I have found it necessary in several instances to repeat important matters, and this I have done to obviate the necessity of continual references to other parts of the book, as well as in some cases to impress the importance of the subject upon the student.

The woodcuts are numerous in proportion to the size of the work, but I consider that they are a very great help to the thorough understanding of the subject.

The old measurements have been purposely omitted in favour of the almost universally adopted metrical system. It is confusing to the learner to have to do with two distinct sets of measurements, and no possible good can accrue from perpetuating the old system of feet and inches.

At the end of the work I have given a list of those authors to whom I have been indebted for much valuable information; and, in conclusion, I take this opportunity of thanking my numerous friends for their help and suggestions.

LIBRARY

CHAPTER I

OPTICS

Light is propagated from a luminous point in every plane and in every direction in straight lines; these lines of direction are called *rays*. Rays travel with the same rapidity so long as they remain in the same medium.

The denser the medium, the less rapidly does the ray of light pass through it.

Rays of light diverge, and the amount of divergence is proportionate to the distance of the point from which they come; the nearer the source of the rays, the more they diverge.

When rays proceed from a distant point such as the sun, it is impossible to show that they are not parallel; and in dealing with rays which enter the eye, it will be sufficiently accurate to assume them to be parallel when they proceed from a point at a greater distance than 6 metres.

A ray of light meeting with a body may be *absorbed*,

reflected, or if it is able to pass through this body it may be *refracted.*

Reflection

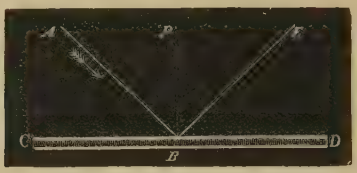
Reflection by a Plane Surface

Reflection takes place from any polished surface, and according to two laws.

1st. The angle of reflection is equal to the angle of incidence.

2nd. The reflected and incident rays are both in the same plane, which is perpendicular to the reflecting surface.

Fig. 1.



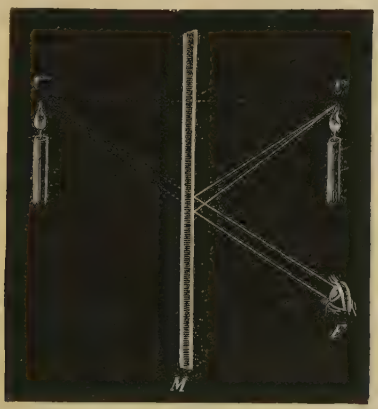
Thus, if A B be the ray incident at B, on the mirror C D, and B E be the ray reflected, the perpendicular P B will divide the angle A B E into two equal parts, the angle A B P is equal to the angle P B E; while A B, P B, and E B lie in the same plane.

When reflection takes place from a plane surface, the image is projected backwards to a distance behind the mirrow equal to the distance of the object in front of it, the image being of the same size as the object.

Thus in Fig. 2 the image of the candle C is formed behind the mirror M, at C′, a distance behind the

mirror equal to the distance of the candle in front of it; an observer's eye placed at E would receive the rays from C as if they came from C′.

FIG. 2.



M. The mirror. C. The candle. C′. The virtual image of the candle. E. The eye of the observer receiving rays from the mirror.

The image of the candle so formed by a plane mirror is called a *virtual image.*

Reflection by a Concave Surface

A concave surface may be looked upon as made up of a number of planes inclined to each other.

Parallel rays falling on a concave mirror are reflected as convergent rays, which meet on the axis at a point (F, Fig. 3) called the *principal focus,* midway between the mirror and its optical centre C. The distance of the principal focus from the mirror is called the focal length of the mirror.

If the luminous point be situated at F, then the diverging rays would be reflected as parallel to each other and to the axis.

If the luminous point is at the centre of the concavity of the mirror (C), the rays return along the same lines, so that the point is its own image.

If the luminous point be at A the focus will be at *a*,

FIG. 3.

and it is obvious that if the luminous point be moved to *a*, its focus will be at A; these two points therefore, A and *a*, bear a reciprocal relation to each other, and are called *conjugate foci*.

If the luminous point is beyond the centre, its conjugate focus is between the principal focus and the centre.

If the luminous point is between the principal focus and the centre, then its conjugate is beyond the centre; so that the nearer the luminous point approaches the principal focus, the greater is the distance at which the reflected rays meet.

If the luminous point be nearer the mirror than the

principal focus (F), the rays will be reflected as divergent, and will therefore never meet: if, however, we continue these diverging rays backwards, they will unite at a point (H) behind the mirror; this point is called the *virtual focus*, and an observer situated in

FIG. 4.

the path of reflected rays will receive them as if they came from this point.

Thus it follows that—

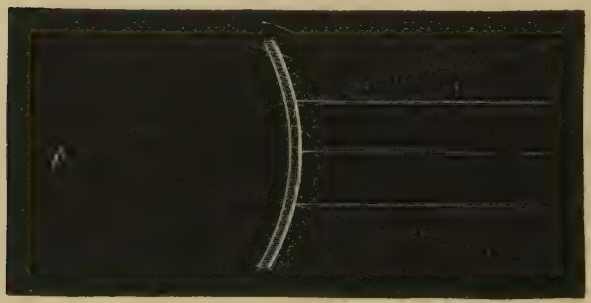
Concave mirrors produce two kinds of images or none at all, according to the distance of the object, as may be seen by looking at one's self in a concave mirror. If the mirror is placed nearer than its principal focus, then one sees an enlarged virtual image, which increases slightly in size as the concave mirror is made to recede; this image becomes confused and disappears as the principal focus of the mirror is reached: on moving the mirror still further away (that is beyond its focus) one obtains an enlarged inverted image, which diminishes as the mirror is still further withdrawn.

Reflection by a Convex Surface

Parallel rays falling on such a surface are reflected as divergent, hence never meet; but if the diverging rays thus formed are carried backwards by lines, then an imaginary image is formed which is called *negative*, and at a point called the *principal focus* (F).

Foci of convex mirrors are therefore virtual; and the image, whatever the position of the object, is always virtual, erect, and smaller than the object.

FIG. 5.



The radius of the mirror is double the principal focus.

Refraction

Refraction by a Plane Surface

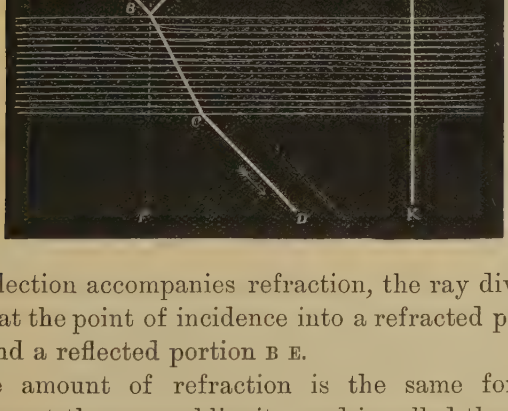
A ray of light passing through a transparent medium into another of a different density is refracted, unless the ray fall perpendicular to the surface separating the two media, when it continues its course without undergoing any refraction (Fig. 6, H K).

A ray is called *incident* before entering the second medium, *emergent* after leaving it.

A ray passing from a rarer to a denser medium is refracted towards the perpendicular; as shown in Fig. 6, the ray A B is refracted at B, towards the perpendicular P P.

In passing from the denser to the rarer medium the ray is refracted from the perpendicular; B D is refracted at C, from P P (Fig. 6).

FIG. 6.



Reflection accompanies refraction, the ray dividing itself at the point of incidence into a refracted portion B C, and a reflected portion B E.

The amount of refraction is the same for any medium at the same obliquity, and is called the index of refraction; air is taken as the standard, and is called 1; the index of refraction of water is 1·3, that of glass 1·5. The diamond has almost the highest refractive power of any transparent substance, and

has an index of refraction of 2·4. The cornea has an index of refraction of 1·3, and the lens 1·4.

The refractive power of a transparent substance is not always in proportion to its density.

If the sides of the medium are parallel, then all rays except those perpendicular to the surface which pass through without altering their course are refracted twice, as at B and C (Fig. 6), and continue in the same direction after passing through the medium as they had before entering it.

If the two sides of the refracting medium are not parallel, as in a prism, the rays cannot be perpendicular to more than one surface at a time.

Therefore every ray falling on a prism must undergo refraction, and the deviation is always towards the base of the prism.

The relative direction of the rays is unaltered (Fig. 7).

FIG. 7. FIG. 8.

If D M (Fig. 8) be a ray falling on a prism (A B C) at M, it is bent towards the base of the prism, assuming the direction M N; on emergence it is again bent at N; an observer placed at E would receive the ray as if it came from K; the angle K H D formed by the two lines

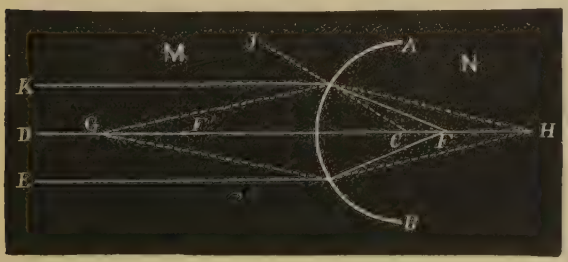
at H is called the *angle of deviation*, and is about half the size of the *principal angle* formed at A by the two sides of the prism.

Refraction by a Spherical Surface

Parallel rays passing through such a surface separating media of different density do not continue parallel, but are refracted, so that they meet at a point called the principal focus.

If parallel rays K, D, E, fall on A B, a spherical surface separating the media M and N of which N is the denser; ray D, which strikes the surface of A B at right angles, passes through without refraction, and is called the *principal axis;* ray K will strike the surface at an angle, and will therefore be refracted towards the perpendicular C J, meeting the ray D at F; so also with ray E, and all rays parallel in medium M. The point F where these rays meet is the *principal focus*, and the

FIG. 9.



distance between the principal focus and the curved surface is spoken of as the *principal focal distance.*

Rays proceeding from F will be paralled in M after

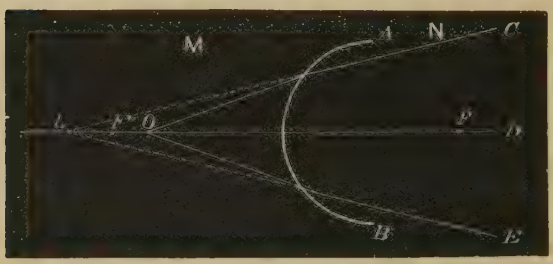
passing through the refracting surface. Rays parallel in medium N will focus at F′, which is called the *anterior focus.*

Had the rays in medium M been more or less divergent, they would focus on the principal axis at a greater distance than the principal focus, say at H; and conversely rays coming from H would focus at G; these two points are then *conjugate foci.*

When the divergent rays focus at a point on the axis twice the distance of the principal focus, then its conjugate will be at an equal distance on the other side of the curved surface.

If rays proceed from a point O, nearer the surface than its principal focus, they will still be divergent after passing through A B, though less so than before, and will therefore never meet; by continuing these

FIG. 10.



rays backwards they will meet at L, so that the conjugate focus of O will be at L, on the same side as the focus; and the conjugate focus will in this case be spoken of as *negative.*

Refraction by Lenses

Refraction by lenses is somewhat more complicated.

A lens is an optical contrivance usually made of glass, and consists of a refracting medium with two opposite surfaces, one or both of which may be segments of a sphere; they are then called *spherical lenses,* of which there are six varieties.

FIG. 11.

1. Plano-convex, the segment of one sphere (Fig. 11, B).

2. Biconvex, segments of two spheres (Fig. 11, A).

3. Converging concavo-convex, also called a converging meniscus.

4. Plano-concave.

5. Biconcave.

6. Diverging concavo-convex, called also a diverging meniscus.

Lenses may be looked upon as made up of a number of prisms with different refracting angles—convex lenses, of prisms placed with their bases together; concave lenses, of prisms with their edges together.

A ray passing from a less refracting medium (as

air) through a lens, is deviated towards the thickest part, therefore the first three lenses, which are thickest at the centre, are called *converging;* and the others, which are thickest at the borders, *diverging.*

FIG. 12.

1 2 3 4 5 6

A line passing through the centre of the lens (called the *optical centre*), at right angles to the surfaces of the lens, is termed the *principal axis,* and any ray passing through that axis is not refracted.

All other rays undergo more or less refraction.

Rays passing through the optical centre of a lens, but not through the principal axis, suffer slight deviation, but emerge in the same direction as they entered. These are called *secondary axes* (Fig. 13). The deviation in thin lenses is so slight that they are usually assumed to pass through in a straight line.

Parallel rays falling on a biconvex lens are rendered convergent; thus in Fig. 14 the rays A, B, C, strike the surface of the lens (L) at the points D, E, F; the centre ray (B) falls on the lens at E perpendicular to its surface, and therefore passes through in a straight line; it also emerges from the lens at right

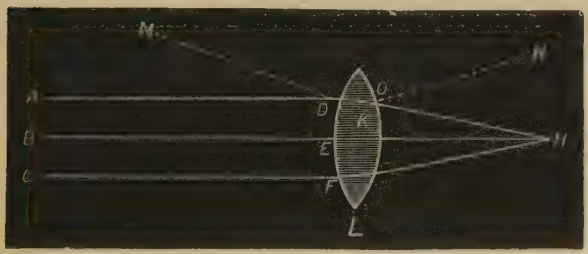
angles to its opposite surface, and so continues its course without deviation; but the ray A strikes the surface of the lens obliquely at D, and as the ray is passing from one medium (air) to another (glass)

FIG. 13.

Lens with secondary axes undergoing slight deviation.

which is of greater density, it is bent towards the perpendicular of the surface of the lens, shown by the dotted line M K; the ray after deviation passes through the lens, striking its opposite surface obliquely at O,

FIG. 14.

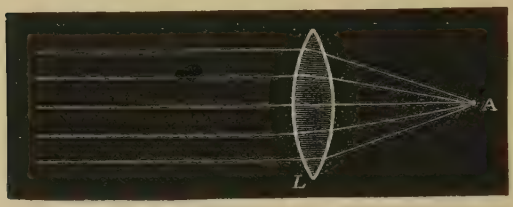


and as it leaves the lens, enters the rarer medium (air), being deflected from the perpendicular N O; it

is now directed to H, where it meets the central ray B H; ray C, after undergoing similar refractions, meets the other rays at H, and so also all parallel rays falling on the biconvex lens (L).

Parallel rays, therefore, passing through a convex lens (L) are brought to a focus at a certain fixed point

FIG. 15.



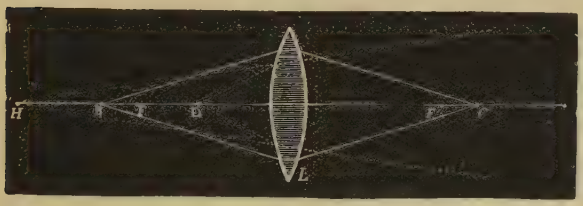
(A) beyond the lens; this point is the *principal focus*, and the distance of this focus from the lens is called the *focal length of the lens.*

Rays from a luminous point placed at the principal focus (A) emerge as parallel after passing through the lens.

Divergent rays from a point (B) outside the principal focus (F, Fig. 16) meet at a distance beyond (F′) the principal focus on the other side of the lens (L), and if the distance of the luminous point (B) is equal to twice the focal length of the lens, the rays will focus at a point (C) the same distance on the opposite side of the lens; rays coming from C would also focus at B: they are therefore called conjugate foci, for we can indifferently replace the image (C) by the object (B), and the object (B) by the image (C).

If the luminous point (D) be between the lens and the principal focus (F), then the rays will issue from the lens divergent, though less so than before entering it; and if we prolong them backwards they will

FIG. 16.



meet at a point (H) further from the lens than the point D; H will therefore be the virtual focus of D, and the conjugate focus of D may be spoken of as *negative*.

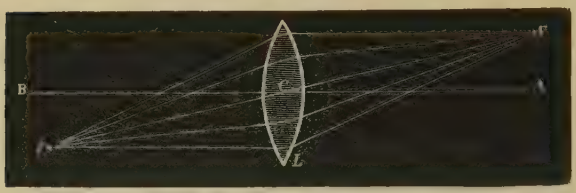
Biconvex lenses have therefore two principal foci, F and F′, one on either side, at an equal distance from the centre.

In ordinary lenses, and those in which the radii of the two surfaces are nearly equal, the principal focus closely coincides with the centre of curvature.

We have assumed the luminous point to be situated on the principal axis; supposing, however, it be to one side of it as at E (Fig. 17), then the line (E F) passing through the optical centre (C) of the lens (L) is a secondary axis, and the focus of the point E will be found somewhere on this line, say at F, so that what has been said respecting the focus of a luminous point on the principal axis (A B) is equally true for points on a secondary axis, provided always that the inclina-

tion of this secondary axis is not too great, when the focus will become imperfect on account of the spherical aberration which will be produced.

Fig. 17.



In biconcave lenses the foci are always virtual, whatever the distance of the object.

Rays of light parallel to the axis diverge after refraction, and if their direction be continued backward they will meet at a point termed the principal focus (Fig. 18, F).

Fig. 18.

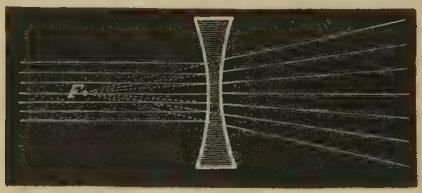


Fig. 19 shows the refraction of parallel rays by a biconcave lens (L); the centre ray B strikes the lens at E perpendicular to its surface, passing through without refraction, and as it emerges from the opposite side of the lens perpendicular to its surface, it

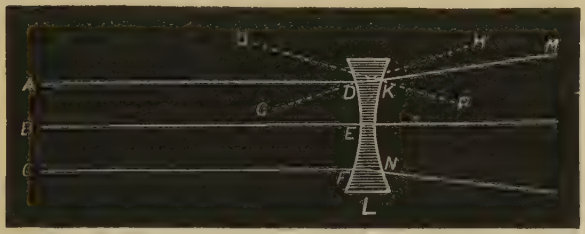
continues in a straight line ; the ray A strikes the lens obliquely at D and is refracted towards the perpendicular, shown by the dotted line G H ; the ray after

FIG. 19.

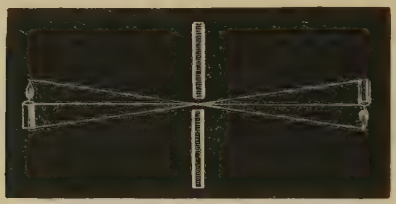


deviation passes through the lens to K, where, on entering the medium of less density obliquely, it is refracted from the perpendicular O P, in the direction K M ; the same takes place with ray C at F and N ; so also with all intermediate parallel rays.

Formation of Images.—To illustrate the formation of images the following simple experiment may be carried out :—Take a screen with a small perforation and place on one side of it a candle, and on the other side a sheet of white cardboard at a suitable distance to receive any image : rays diverge from the candle in all directions, most of those falling on the screen are intercepted by it ; but some few pass through the perforation and form an image of the candle on the cardboard, the image being inverted because the rays cross each other at the orifice. It can further be shown that when the candle and cardboard are equally distant from the

perforated screen, the candle flame and its image will be of the same size. If the cardboard be moved further from the screen the image is enlarged, if it be moved nearer it is diminished; if we make a

Fig. 20.



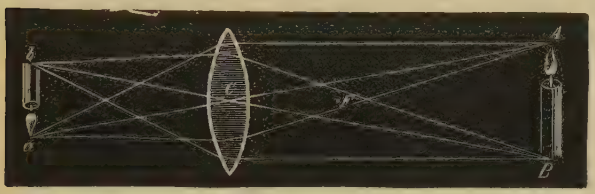
dozen perforations in the screen, a dozen images will be found on the cardboard, if a hundred then a hundred; but if the apertures are so close together that the images overlap, then instead of so many distinct images we get a general illumination of the cardboard.

The image of an object is the collection of the foci of its several points; the images formed by lenses are, as in the case of the foci, real or virtual. Images formed, therefore, by convex lenses may be real or virtual.

In Fig. 21, let A B be a candle situated at an infinite distance; from the extremities of A B draw two lines passing through the optical centre (C) of a biconvex lens, then the image of A will be formed somewhere on the line A C *a* (termed a secondary axis), say at *a*; the image of B will be formed on the line B C *b*, say at *b*; therefore *b a* is a small inverted image

of the candle A B, formed at the principal focus of the convex lens. Had the candle been placed at twice the focal distance of the lens, then its inverted image

FIG. 21.



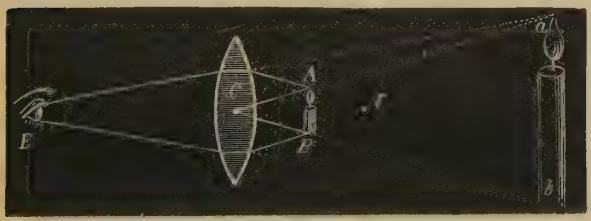
Real inverted image formed by convex lens.

would be formed at a corresponding point on the opposite side of the lens, and would be of the same size as the object.

If the candle be at the principal focus (F), then the image is at an infinite distance, the rays after refraction being parallel.

If, however, the candle (A B) be nearer the lens than

FIG. 22.



Virtual image formed by convex lens.

the focus, then the rays which diverge from the candle, will, after passing through the convex lens, be still

divergent, so that no image is formed; an eye placed at E would receive the rays from A B as if they came from *a b*; *a b* is therefore a virtual image of A B, erect and larger than the object, and formed on the same side of the lens as the object.

Images formed by biconcave lenses are always virtual, erect, and smaller than the object. Let A B

FIG. 23.

Virtual image formed by concave lens.

be a candle, and F the principal focus of a biconcave lens; draw from A B two lines through C, the optical centre of the lens, and lines also from A and B parallel to the axis; after passing through the lens they diverge and have the appearance of coming from *a b*, which is therefore the virtual image of A B.

A real image can be projected on to a screen, but a virtual one can only be seen by looking through the lens.

CHAPTER II

REFRACTION. ACCOMMODATION. CONVERGENCE

The eye may be looked upon as an optical instrument, a sort of photographic camera, designed to produce by means of its refracting system a small and inverted picture of surrounding objects upon the retina; the stimulation produced by this picture on the retina is conveyed through the optic nerve to the ganglion cells of the cortex, that part known as the optical area; this excitation of the ganglion cells becomes sensation, and thus it is here that the object seen comes within the domain of consciousness, and the brain interprets the retinal impressions transmitted to it. Immediately behind the transparent retina is a layer of pigment, which absorbs some of the rays of light as soon as the image is formed; were this not so the rays would be reflected to other parts of the retina, and cause much dazzling, considerably interfering with vision; this is the case in those persons who have a congenital absence of pigment, and who are known as albinos.

The refracting system of the eye is so arranged, that very little spherical or chromatic aberration

takes place, as is the case with ordinary optical instruments.

For distinct and accurate binocular vision the following conditions are necessary :

1. That a well-defined inverted image be formed on the layer of rods and cones at the yellow spot of each eye.

2. That the impression there received be conveyed to the brain.

In a work of this character the first of these conditions alone concerns us, and for the carrying out of this—the media being transparent—three important factors call for a separate description, viz.

Refraction.
Accommodation.
Convergence.

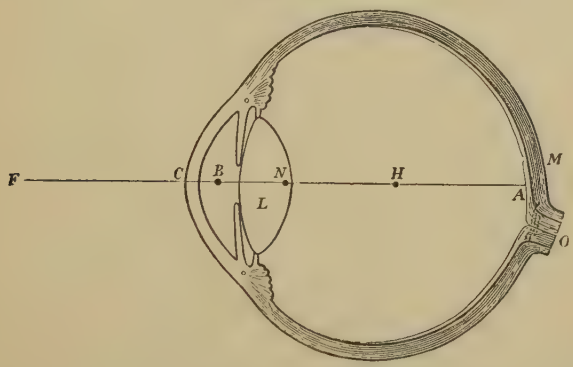
Refraction.—This term is used to express the optical condition of the eye in a state of rest. There are three refracting surfaces in the eye—the anterior surface of the cornea, the anterior surface of the lens, and the anterior surface of the vitreous; and three refracting media—the aqueous, the lens, and the vitreous. These together make up the dioptric system, and may for the sake of simplicity be looked upon as equal to a convex lens of about 23 mm. focus. What was said about convex lenses applies equally to the eye as an optical instrument.

A ray of light falling on the cornea does not, however, follow the simple direction we might imagine when considering the eye merely as a lens of 23 mm.

focus: the eye must be looked upon as a compound refracting system, composed of a spherical surface and a biconvex lens. To enable us to understand the course of a ray of light through the eye, it is necessary to be acquainted with the cardinal points of this compound system. Too much space would be occupied to explain how the position of these points is arrived at, but it suffices to say that, having first found the cardinal points of the cornea and then those of the lens, the cardinal points of the eye will be the result of these two systems together.

The cardinal points of the eye are six in number, *two principal points, two nodal points,* and *two principal foci.*

FIG. 24.



In the above diagram of the emmetropic eye the cardinal points of this compound system are shown, all situated on the optic axis (F A): at B are two principal points situated so closely together in the anterior chamber that they may conveniently be looked upon

as one point; at N are two nodal points, also close together,—for simplicity we shall consider them as one point; at F is the first principal focus, at A the second principal focus. We then have the following: C, the cornea; L, the lens; M, the macula; O, the optic nerve; F A, the optic axis; B, the principal point; N, the nodal point; H, the centre of rotation of the eye, 9·8 mm. in front of the retina; A, the second principal focus; and F, the first principal focus.

The *nodal points* correspond nearly to the optical centre of the refracting system, the axis ray passing through these points is not refracted; every ray directed to the first nodal point appears after refraction to come from the second point, and continues in the same direction to that which it first had: the nodal points in the eye are situated about 7 mm. behind the cornea (Fig. 24, N).

The principal points.—When an incident ray passes through the first principal point, the corresponding emergent ray passes through the second principal point, but the incident and emergent rays are not parallel; the principal points are situated about 2 mm. behind the cornea (Fig. 24, B).

The *first principal focus* is that point on the axis where rays parallel in the vitreous meet; this point is about 13·7 mm. in front of the cornea (Fig. 24, F).

The *second principal focus* is that point on the axis where parallel rays meet after passing through the eye, 22·8 mm. behind the cornea (Fig. 24, A).

A luminous point placed above the principal axis has its image formed on the retina below this axis; and

inversely, the image of a point below the principal axis will be formed above it. If we replace these two points by an object the same thing occurs, and we get an *inverted* image (Fig. 25): it is essential that the method of formation of these inverted images be thoroughly understood.

From every point of an object A B C proceed divergent rays. Some of those rays coming from A, pass through the pupil, and being refracted by the dioptric system, come to a focus on the retina at *a*; some coming from B, focus at *b*, and some from C at *c*. In

FIG. 25.

the same way rays come from every part of the object as divergent rays, and are brought to a focus on the retina; so that the retina, being exactly at the focal distance of the refracting system, receives a well-defined inverted image.

Much has been said and written as to why images which are formed in an inverted position on the retina should be seen upright, and all sorts of ingenious explanations have from time to time been given. The whole thing is entirely a matter of education and ex-

perience, which is supplemented and corroborated by the sense of touch. We have no direct cognizance of the image on the retina, nor of the position of its different parts, but only of the stimulation of the retina produced by the image; this stimulation is conducted by the optic nerve to the brain, producing there certain molecular changes. We do not actually see the retinal image, but the eye receives the rays emanating from the object looked at, and we refer the sensation in the direction of these rays; thus, if an image is formed on the upper part of our retina, we refer the sensation downwards from which the rays must have come.

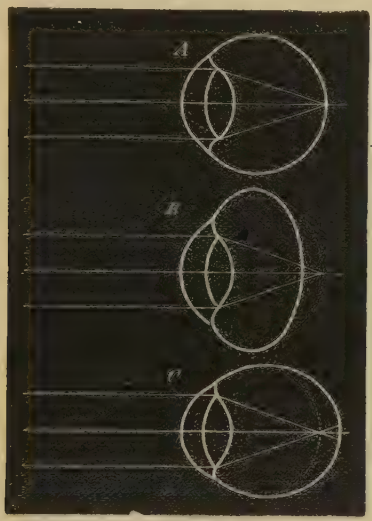
The great advantage of inverted images is, that for a given-sized pupil a much larger retinal picture can be formed than would be the case if no inversion took place; for in the latter case all images must necessarily occupy a smaller space on the retina than the size of the pupil.

The refraction of the eye is said to be normal when parallel rays are united exactly on the layer of rods and cones of the retina; in other words, when the retina is situated exactly at the principal focal distance of the refracting system of the eye. This condition is called *emmetropia* (ἐμ, within; μέτρον, measure; ὤψ, the eye) (Fig. 26, A). If parallel rays are focussed behind or in front of the retina, then the term *ametropia* (α, priv.; μέτρον, measure; ὤψ, the eye) is used, and of this there are two opposite varieties:

Hypermetropia, when the eyeball is so short that

parallel rays are brought to a focus behind the retina (Fig. 26, B).

FIG. 26.



A. Emmetropic eye. B. Hypermetropic eye. C. Myopic eye.

Myopia, when the eyeball is too long, so that parallel rays focus in front of the retina (Fig. 26, C).

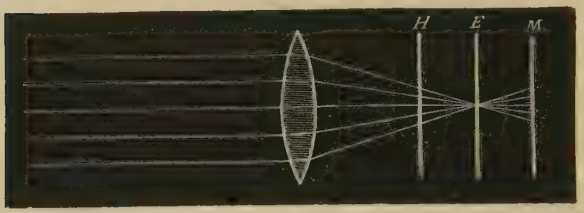
Emmetropia in a strict mathematical sense is very rare.

If we represent the eye by a biconvex lens, and the retina by a screen; then it will correspond to emmetropia when the screen is situated at the principal focus of the lens, as E, Fig. 27; we represent hypermetropia (H) by bringing forward the screen, and myopia (M) by moving it further away from the lens.

In all eyes, vision ranges from the far point or

punctum remotum (which in the emmetropic eye is at infinity) to the near point or punctum proximum.

Fig. 27.



Convex lens of 23 mm. focus. Parallel rays focus at E (emmetropia) on the screen, forming a well-defined image of the object from which rays come; at H (hypermetropia) they form a diffusion patch instead of an image. M (myopia), also a diffusion patch, the rays having crossed and become divergent.

The near point varies in the normal eye according to the amount of the accommodation, receding gradually as age advances; when it has receded beyond 22 cm. (which usually occurs in the emmetropic eye about the age of forty-five) the condition is spoken of as *presbyopia*.

Infinity is any distance beyond six metres, the rays coming from a point at or beyond that distance being parallel or almost so.

The emmetropic eye, therefore, has its far point, or punctum remotum, situated at infinity; the hypermetropic eye has its punctum remotum beyond infinity, and the myopic eye has its punctum remotum at a finite distance.

Generally the two eyes are similar in their refrac-

tion, though sometimes there is a very great difference. One eye may be hypermetropic, the other myopic; or one emmetropic, the other ametropic. *Anisometropia* is the term used when the two eyes thus vary in their refraction.

There may be differences also in the refraction of the different meridians of the same eye—*astigmatism*.

In all forms of ametropia the acuteness of vision is liable to be diminished. The visual acuteness usually decreases slightly as age advances, without any disease.

The visual acuteness refers always to central vision. The yellow spot is the most sensitive part of the retina, and the sensibility diminishes rapidly towards the periphery. The acuteness is measured by the size of the visual angle, that is the angle formed at the posterior nodal point, which point closely coincides with the posterior surface of the lens, and is about 15 mm. in front of the yellow spot.

In Fig. 28, let C D be an object for which the eye is

FIG. 28.

accommodated. The lines C *c*, D *d*, drawn from the extremities of the object, cross at the nodal point N. The angle C N D will be the visual angle under which

the object C D is seen. The size of the angle depends upon the distance of the object as well as upon its magnitude, and the size of the image thus formed on the retina will also depend upon the antero-posterior length of the eyeball.

Thus an object A B, which is as large as C D, but nearer to the eye, will be seen under a larger angle, the angle A N B being greater than the angle C N D. It is also clear that the image formed on the retina will be smaller at 1, when the antero-posterior diameter of the eye is less, as in hypermetropia, than it is at 2 in emmetropia, and that it will be larger in myopia, as at 3, where the eyeball is elongated. It is, therefore, easy to understand that a patient may be able to read the smallest type and still have some defect of refraction, unless the type be read at its proper distance (see Fig. 35).

It is by the unconscious comparison of things of known size, and the amount of accommodation brought into play, that we are able to estimate the distance of objects, and not by the visual angle alone.

Objects must therefore be of a certain size, and it has been proved that to enable us to see a complex figure like a letter distinctly, each part of the figure must be separated from the other parts by an interval equal to not less than the arc subtending an angle of 1′ at the nodal point.

It has been shown (Fig. 26, B) that in the hypermetropic eye in a state of rest, parallel rays are brought to a focus behind the retina, so that instead of a clear, well-defined image, we get a circle of dif-

fusion. Convex glasses render parallel rays passing through them convergent, so that by placing a lens of the right strength in front of the hypermetropic eye, we bring forward its focus on to the retina.

In myopia (Fig. 26, c) the focus for parallel rays is in front of the retina; concave glasses render parallel rays passing through them divergent, so that the proper concave glass will carry back the focus on to the retina.

Lenses.—The lenses used for estimating the visual acuteness consist of two kinds, spherical and cylindrical. *Spherical lenses* were until recently numbered according to their radii of curvature, which was considered as equal to their focal length in inches, a glass of 1-inch focus being taken as a standard. To this plan there were several objections. The standard glass being a strong one, weaker glasses had to be expressed in fractions. Thus a glass of 4-inch focus was one fourth the strength of the standard 1 inch, and was expressed as $\frac{1}{4}$. In addition to the trouble and inconvenience of working with fractions, the intervals between the lenses were most irregular, and, moreover, the inches of different countries vary. At the Ophthalmological Congress in 1872 it was decided to adopt a metrical scale of measurement. A lens of 1-metre focus is taken as the unit, and is called a dioptre; a weak instead of a strong glass therefore becoming the unit, a lens of two dioptres is twice the strength of the former, and has a focal length of half a metre. Thus each lens is numbered according to its refracting power, and not, as in the old system, according to its

focal length; so that we have a series composed of equidistant terms. The numbers 1 to 20 indicate the uniformly increasing power of the glasses.

The focal length of a lens is not expressed in the dioptric measurement; we have only to remember that it is the inverse of the refracting power, so that by dividing 100 cm. by the number of the lens we obtain its focal length in centimetres: for example, if the strength of the lens be 2 D., then the focal length will be 50 cm.; if 10 D., then 10 cm.

The intervals between dioptres is somewhat large, so that decimals, ·25, ·50, ·75 of a dioptre, are introduced; these work easily.

Convex glasses magnify, and concave ones diminish the size of objects.

The *cylindrical lens* still remains to be mentioned; it consists of a lens one surface of which is usually plane while the other is the segment of a cylinder, and may be either convex or concave: if a convex cylinder be held vertically, the vertical meridian will be plane, exercising no influence on rays passing through it in that meridian; while the horizontal meridian will be convex, and will act as such on rays passing through it. The axis of the cylinders is usually indicated by a portion of the lens on each side being ground parallel to its axis.

Accommodation.—In the normal eye, in a condition of complete repose, parallel rays come to a focus exactly on the rods and cones of the retina, and the object from which the rays come is therefore seen distinctly.

Rays from a near object proceed in a divergent direction, and come to a focus behind the retina; the object would not then be clearly seen unless the eye possessed within itself the power of bringing rays which are more or less divergent into union on the retina.

This power of altering the focus of the eye is called *accommodation*, and is due to an alteration in the form of the lens. That the eye possesses this power can easily be proved in many ways, apart from the conscious muscular effort; perhaps as simple a way as any to demonstrate it to one's self is to look through a net held a short distance off at some distant object. Either the net or the object can be seen distinctly, but not both at once. If the meshes of the net be looked at, then the distant object becomes indistinct, and on looking at the object the meshes become confused.

Accommodation, therefore, increases the refraction of the eye, and adapts it to near objects. The changes which take place in the lens during accommodation are—

1st. The anterior surface becomes more convex and approaches the cornea.

2nd. The posterior surface becomes slightly more convex, but remains the same distance from the cornea. That these changes take place may be proved in the following manner:—A lighted candle, or other convenient object, being held on one side of the eye, so as to form an angle of 30° with its visual axis, an observer looking into the eye from a corresponding

position on the other side, will see three images of the flame: the first upright, formed by the cornea; the second larger, upright, and formed by the anterior surface of the lens; the third smaller and inverted, formed by the posterior surface of the lens. When accommodation is put in force, images one and three remain unchanged in shape and position; image two, which is that formed by the anterior surface of the lens, becomes smaller, more distinct, and approaches image one, proving that this surface of the lens has become more convex and has approached the cornea. In an emmetropic eye adapted for infinity, it has been proved that the radius of curvature of the anterior surface of the lens is 10 mm.; when accommodated for an object 13·5 cm. off it is changed to 6 mm.

During accommodation the pupil becomes smaller, the central part of the iris advances, while the peripheral part slightly recedes.

The alteration in the shape of the lens is due to the contraction of the ciliary muscle, which draws forward the choroid, thereby relaxing the suspensory ligament, and allowing the elasticity of the lens to come into play. This elasticity is due to the peculiar watch-spring arrangement of the lens fibres.

When the ciliary muscle is relaxed, the suspensory ligament returns to its former state of tension, and so tightens the anterior part of the capsule, flattening the front surface of the lens.*

* Another theory of accommodation is Tscherning's, whose experiments have led him to believe that when the ciliary muscle contracts it increases the tension of the zonula, and alters the lens surface from a spherical to a hyperboloid form.

When the muscle is relaxed to its uttermost, the lens has assumed its least convexity, and the eye is then adapted for its far point (*punctum remotum*) (*r*).

In this condition the eye is spoken of as being in a state of complete repose.

In the emmetropic eye the punctum remotum is situated at infinity.

FIG. 29.

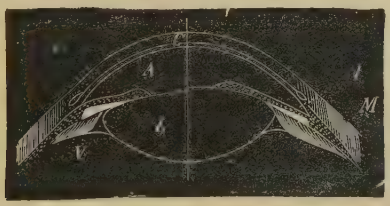


Diagram of lens, cornea, &c. The right half is represented as in a state of accommodation, the left half at rest. A. The anterior chamber. C. The cornea. L. The lens. V. The vitreous humour. I. The iris. M. Ciliary muscle.

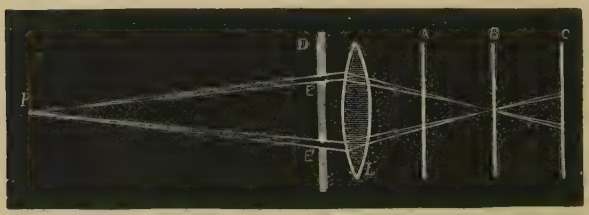
When the ciliary muscle has contracted as much as it can, the lens has assumed its greatest convexity, and its maximum amount of accommodation is in force. The eye is now adapted for the nearest point which can be seen distinctly; this is called the *punctum proximum* (*p*).

The position of the punctum proximum can be determined in several ways; the ordinary plan is to place in the patient's hand the small test type, and note the shortest distance at which he can read No. 1 with each eye separately. Or we may measure its position with the wire optometer, which consists of a steel

frame crossed by thin vertical wires; this is supported in a handle to which a tape measure is attached; the tape is placed against the temple, and held there while the frame is made gradually to recede from the patient's eye we are examining, stopping as soon as the wires become distinct, and reading off the number of centimetres on the measure. Another excellent plan by which to find the position of the punctum proximum is that of Scheiner: close in front of the eye we wish to examine is placed a card pierced with two small pinholes, which must not be further apart than the diameter of the pupil; through these two holes the patient is directed to look at a pin held about one metre away (the other eye is of course excluded from vision during the experiment); the pin will be clearly and distinctly seen. We then gradually approach it to the eye: at a certain place it will become double: the point at which the pin ceases to appear single will be the punctum proximum.

In Fig. 30 the biconvex lens L represents the eye,

FIG. 30.



D the perforated card, P the pin, E E′ the two sets of rays from P, which focus exactly at B, the retina. If,

however, the pin be brought nearer, so that the accommodation is unable to focus the two sets of rays, they will form, instead of one, two images of the pin on the retina as at A. These will be projected outwards as crossed images.

The space between the punctum remotum and the punctum proximum is called *the range of accommodation.*

The force necessary to change the eye from its punctum remotum to its punctum proximum is styled the *amplitude of accommodation.* The amplitude of accommodation, therefore, is equal to the difference between the refracting power of the eye when in a state of complete repose, and when its maximum amount of accommodation is in force, and may be expressed by the formula

$$a = p - r.$$

A convex glass placed in front of the eye produces the same effect as accommodation, *i. e.* it increases its refraction and adapts the eye for nearer objects. We can easily understand that the lens which enables an eye to see at its near point without accommodating is a measure of the amplitude of accommodation, giving to rays which come from the near point a direction as if they came from the far point.

The amplitude of accommodation is much the same in every kind of refraction. If we wish to measure it in an *emmetrope,* we have merely to find the nearest point at which the patient can read small print. A lens whose focal distance corresponds to this is a measure of the amplitude of accommodation. Thus,

supposing 20 cm. the nearest distance at which he is able to read small print, we divide this into 100 cm. to find the focal distance of the lens ($\frac{100}{20} = 5$ D.); and in this case a lens of 5 D. is the measure of the amplitude of accommodation.

Or we can measure it in an inverse manner by looking at a distant object through a concave glass; the strongest with which we can see this distant object distinctly is the amplitude of accommodation, the concave lens giving to parallel rays coming from the distant object such an amount of divergence as if they came from a point situated at the principal focal distance of this glass.

Therefore the amplitude of accommodation in emmetropia is equal to the refraction when adapted to its punctum proximum, and may be expressed by the formula

$$a = p - \infty^*$$
$$\text{or } a = p - 0$$
$$\text{or } a = p$$

The Accommodation of Hypermetropes.—A hypermetrope requires some of his accommodation for distant objects; we must therefore, in order to find the amplitude of accommodation in his case, add on to the lens whose focal length equals the distance of the near point, that convex lens which enables him to see distant objects without his accommodation, and we express it by the formula

$$a = p - (-r) = p + r.$$

Thus, to take an example, we will assume the

* ∞ is the sign for expressing infinity.

patient's near point to be 25 cm. ($\frac{100}{25} = 4$ D.), and that he has to use 4 D. of accommodation for distant objects; then the amplitude of his accommodation would be 4 D. + 4 D. = 8 D.

$$a = 4\ D. - (-\ 4\ D.) = 8\ D.$$

The Accommodation of Myopes.—In a myope we have to subtract the glass which enables him to see clearly distant objects, from that whose focal length equals the distance of the near point. The formula will then be

$$a = p - r.$$

Thus, to find the amplitude of accommodation in a myope of 2 D., the near point being at 10 cm., we subtract from ($\frac{100}{10} = 10$) 10 D. the amount of the myopia, 2 D., and the resulting 8 D. is therefore the amplitude of accommodation.

$$a = 10\ D. - 2\ D. = 8\ D.$$

Hence it is obvious that, with the same amplitude of accommodation, the near point is further away in hypermetropia than in emmetropia, and further in emmetropia than in myopia. Thus an emmetrope, with an amplitude of accommodation of 5 D., would have his near point at ($\frac{100}{5} = 20$) 20 cm.; a hypermetrope of 2 D., whose amplitude equalled 5 D., would require to use 2 D. of his accommodation for distance, leaving him 3 D., which would bring his near point to ($\frac{100}{3} = 33$) 33 cm.; and a myope of 2 D., who would require a concave glass of this strength to enable him to see at a distance, would have a near point of 14 cm. ($\frac{100}{7} = 14$) with the same amplitude.

Accommodation is spoken of as *absolute, binocular,* and *relative.*

Absolute is the amount of accommodation which one eye can exert when the other is excluded from vision.

Binocular, that which the two eyes can exert together, being allowed at the same time to converge.

Relative, that which the two eyes can exert together for any given convergence of the visual lines.

FIG. 31.

Dioptres.

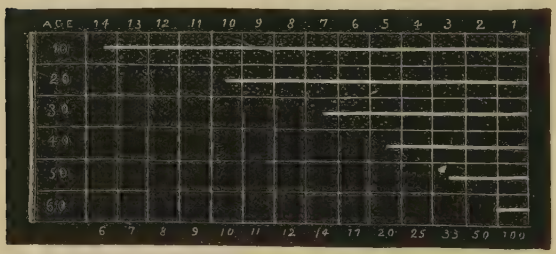


Diagram showing by the number of squares through which the thick lines pass, the amplitude of accommodation at different ages in emmetropia. The figures above represent the amount of accommodation; those below, the near point; and those on the left, the age of the individual.

Fig. 31 diagrammatically represents the amplitude of accommodation in emmetropia.

As age advances the elasticity of the lens diminishes, the accommodation therefore becomes less, and the near point gradually recedes. These changes commence at a very early age, long before the individual has come to maturity.

The following table gives the amplitude of accòmmodation at different ages as shown in Fig. 89, p. 188.

Years.	Amplitude of accommodation
10	14 D.
15	12 D.
20	10 D.
30	7 D.
40	4·5 D.
50	2·5 D.
60	1 D.
75	0

Convergence.—This is the remaining element of distinct binocular vision, and with this function the accommodation is very intimately linked, so that usually for every increase of the convergence a certain increase in the accommodation takes place.

Convergence is the power of directing the visual axes of the two eyes to a point nearer than infinity, and is brought about by the action of the internal recti muscles.

When the eyes are completely at rest, the optic axes are either parallel, or more usually slightly divergent. The angle thus formed between the visual and the optic axis is called the angle *a*, and varies according to the refraction of the eye. In emmetropia the angle is usually about 5°; in hypermetropia it is greater, sometimes as much as 7° or 8°, giving to the eyes an appearance of divergence; in myopia the angle is less, often about 2°, or the optic axis may, even in extreme cases, fall on the inside of the visual axis,

when the angle a is spoken of as negative (p. 203); so that in myopia there is frequently an appearance of convergence, giving one the idea of a convergent squint; hence the mere look of the patient's eyes with regard to their axes is not always quite reliable.

The object of convergence is the directing of the yellow spot in each eye towards the same point, so as to produce singleness of vision; diplopia, or double vision, at once results when the image of an object is formed on parts of the retina which do not exactly correspond in the two eyes.

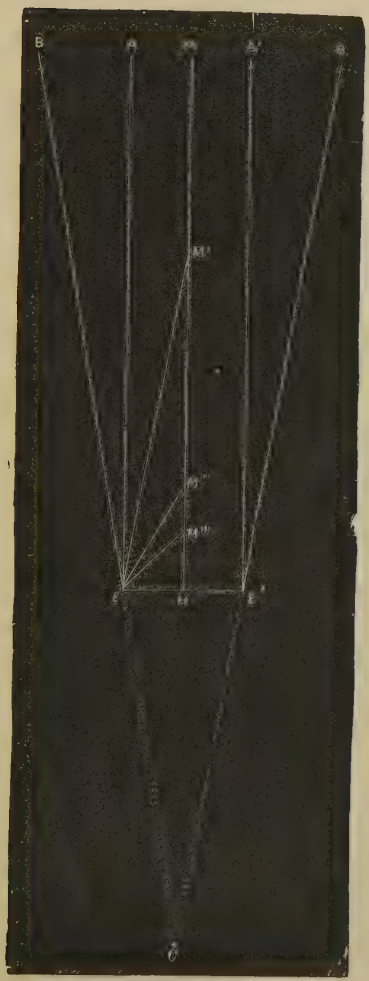
To test the power of convergence prisms are held with their bases outwards. The strongest prism which it is possible to overcome, that is the prism which does not produce diplopia on looking through it at a distant object, is the measure of the convergence, and varies in different persons, usually between prisms of 20° and 30°, divided between the two eyes. This is the relative convergence for infinity.

In considering convergence we have not only to bear in mind the condition of the internal recti muscles, but also the state of equilibrium produced by them and the action of their antagonists—the external recti.

The nearer the object looked at, the more we have to converge, and the greater the amount of accommodation brought into play. Hence, on converging to any particular point, we usually also involuntarily accommodate for that point, the internal recti and ciliary muscles acting in unison.

Nagel has proposed a very simple and convenient

Fig. 32.



plan, by which we may express the convergence in metres, calling the angle formed by the visual and median lines, as at M′, the *metrical angle*. In Fig. 32 E, E′ represent the centres of rotation for the two eyes; E H E′ is the base line between the centres. When the eyes are fixed on some distant object, the visual lines are parallel or almost so, as E A, E′ A′; the angle of convergence is then at its minimum, and the convergence is said to be adapted for its *punctum remotum;* this then, being at infinity, is expressed C* = ∞.

If the eyes be directed to an object one metre away, the metrical angle E M′ H equals one, *i. e.* C = 1. If the object is 50 cm. off, then C = 2; if 10 cm., then ($\frac{100}{10}$ = 10) C = 10. If the object had been beyond 1 metre (our unit), but not at infinity, say 4 metres, then C = $\frac{1}{4}$.

When the visual lines, instead of being parallel, diverge, then the punctum remotum is found by continuing these lines backwards till they meet at c, behind the eye; the convergence is then spoken of as *negative*.

When the eyes are directed to the nearest point at which they can see distinctly, say at M‴, the angle of convergence is at its maximum, and it is said to be adapted for its *punctum proximum*.

The distance between the punctum proximum and the punctum remotum is the *range of convergence*.

The amplitude of convergence is the whole converg-

* C is the sign for convergence.

ence that can be put in force, and we express it by the formula

$$c = p - r.$$

The *punctum remotum* of convergence is seldom situated at a finite distance: sometimes it is exactly at infinity, but in the majority of cases it is situated beyond infinity, *i. e.* the visual lines diverge slightly. In order to measure this divergence, and so obtain the punctum remotum of convergence, we place before the eyes prisms with their bases inwards (abducting prisms), and the strongest through which the person is still able to see singly is the measure of the negative convergence.

Prisms are numbered in degrees according to the angle of the prism. The deviation produced by a prism is equal to half its angle; thus prism 8 will produce a deviation of the eye of 4°, and prism 20 a deviation of 10°.

When a prism is placed before one eye, its action is equally divided between the two eyes.

To take an example: if an abducting prism of 8° placed before one eye (or what is the same thing, 4° before each eye) be found to be the strongest through which a distant object can be seen singly, then each eye in our example has made a movement of divergence equal to 2°, and the punctum remotum of convergence in this case is therefore negative, and is expressed − 2°. By referring to the table on page 49 it will be seen that when the centres of rotation of the eyes are 6·4 cm. apart, then the metre angle

equals 1° 50′, so we reduce the 2° to metre angles, thus:

$$\frac{2^\circ}{1^\circ\ 50'} = \frac{120}{110} = 1{\cdot}09\ m\ a\ ;$$

or it is sufficient to remember to divide the prism placed before one eye by seven; thus in our example we should divide prism 8° by seven, and this would give us approximately the same result.

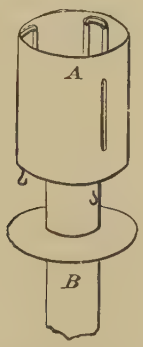
Another excellent plan for finding the punctum remotum of convergence is by Maddox's test, which consists of a small glass rod placed behind a stenopaic slit; when this is held horizontally before the right eye, and the flame of a candle viewed from a distance of 6 metres with both eyes open, the left eye receives the image of the flame, while the right receives the image which is drawn out by the rod into a long vertical strip of light; and since the image received by the two eyes is very different, there is no tendency to fusion, and the eyes take up their position of rest. A suitable scale placed behind the candle will give us the amount of convergence or divergence in metre angles, according to the position occupied by the streak of light on the scale. Should the patient be a myope or hypermetrope he should wear his correction when this test is applied.

To find the punctum proximum of convergence, hold a prism, base outwards (adducting prism), before one eye, and the strongest which can be so employed without producing diplopia, divided between the two eyes, gives the punctum proximum of convergence in degrees. But the accommodation must be stimulated

at the same time by means of a concave glass, otherwise we only obtain the relative punctum proximum. This can be reduced to metre angles as before.

Or a simpler plan is to measure it with Landolt's ophthalmo-dynamometer, which is a small instrument consisting of a black metallic cylinder, A, made so as to fit upon a candle, B. The cylinder has a vertical slit ·3 mm. in breadth, covered by ground glass: the candle being lighted, this slit forms a luminous line,

FIG. 33.



and will serve as a fixation object. A tape measure is conveniently attached, being graduated in centimetres on one side, and on the other in the corresponding numbers of metre angles.

To find the punctum proximum of convergence, the measure is drawn out to about 70 cm., its case being held beside one of the eyes of the patient, while the object of fixation is placed in the median line. If the illuminated line is seen singly, by pressing the knob

of the case the spring rolls up the tape, and the fixation object is brought nearer the eye. So soon as the patient commences to see double, the nearest point of convergence is obtained, and the maximum of convergence is read off the tape in metre angles. This experiment should be repeated several times.

In a normal case the minimum of convergence is usually about $-1\ m\,a$, the maximum $9{\cdot}5\ m\,a$; so that the amplitude of convergence equals $10{\cdot}5\ m\,a$.

We know that the accommodation increases the nearer the object approaches, hence we see that both the convergence and accommodation increase and decrease together; and in recording the convergence in the manner proposed by Nagel, it will be seen that in the emmetropic eye the number which expresses the metrical angle of convergence expresses also the state of refraction for the same point—this is a great advantage. Thus, when looking at a distant object, the angle of convergence is at infinity, $C = \infty$; and the refraction is also at infinity, $A = \infty$. When the object is at 1 metre, the angle of convergence $= 1$, and the amount of accommodation put into play $= 1$ D. When the object is at 25 cm., then the angle of convergence $= 4$, and the amount of accommodation $= 4$ D.

The amplitude of convergence is somewhat greater than the amplitude of accommodation, passing it both at its punctum remotum and its punctum proximum.

The following table shows the angle of convergence in degrees, for different distances of the object, when the eyes are 6·4 cm. apart:

Distance of the object from the eyes.	The metrical angle.	Value expressed in degrees.
1 metre ...	1 ...	1° 50′
50 cm. ...	2 ...	3° 40′
33 „ ...	3 ...	5° 30′
25 „ ...	4 ...	7° 20′

Although accommodation and convergence are thus intimately linked together, it can very easily be proved that they may have a separate and independent action. If we suspend the accommodation with atropine, the convergence is not interfered with; or an object at a certain distance being seen clearly without a glass, it can still be seen distinctly with weak concave and convex glasses, without any alteration of the convergence.

It may, therefore, be stated that although the accommodation and convergence are intimately associated, they may be independent of each other to a certain degree, so as to meet ordinary requirements; thus for instance, as age advances changes take place

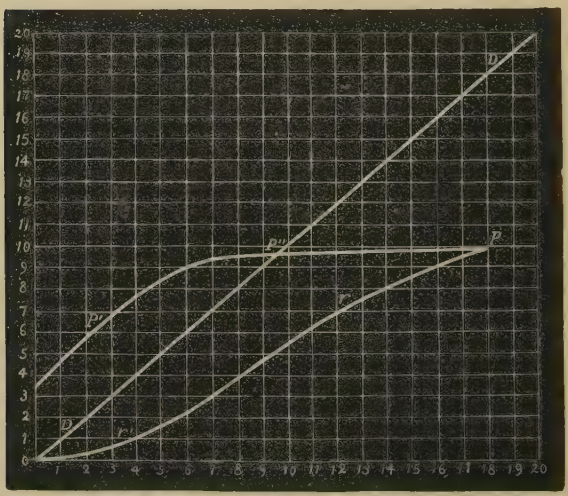
BOSTON MEDICAL LIBRARY

in the lens which necessitate a stronger contraction of the ciliary muscle to produce the requisite change in the accommodation, while the convergence remains the same.

It is obvious also that the relations between accommodation and convergence must necessarily be very different in ametropia, and this relation will be again referred to when treating the various errors of refraction in detail.

The following diagram (Fig. 34) shows the relative amount of accommodation for different points of con-

Fig. 34.



vergence in an emmetrope aged fifteen. The amount of accommodation in excess of the metrical angle of

convergence is called *positive*, and the amount below *negative*.

The diagonal D D represents the convergence from infinity to 5 cm.; it is also a record of the accommodation. The line P P′ P″ indicates the maximum accommodation for each point of convergence, and the line *r r′* the minimum. The numbers on the left and below the diagram are dioptres and metrical angles of convergence; thus, when the visual lines are parallel, it will be seen that 3·5 D. of positive accommodation can be put into play, *i. e.* the object can still be seen distinctly with a concave glass of that strength; 3·5 D. is therefore the relative amplitude of accommodation for convergence adapted to infinity; or the metrical angle C being 5, which is a distance of 20 cm. away, the accommodation for that point would equal 5 D.; the positive amount that can be put in force while the angle of C remains the same would be 3 D., and the negative also 3 D., the object being seen clearly with a concave or convex glass of 3 D., therefore the relative amplitude of accommodation for C 5 is 6 D. When the angle C = 10 or any larger angle, the accommodation that can be put in force will be seen to be entirely on the negative side.

Thus, the convergence being fixed, the amount of accommodation which can be brought into play for that particular point is the sum of the difference between the strongest concave and convex glass employed.

The eye being accommodated for an object at a certain distance, the amount of convergence for that

particular point may be measured by placing in front of the eyes prisms, bases outwards; the strongest prism through which the object is still seen singly is the measure of the positive part of the amplitude of convergence. Prisms, bases inwards, give us the negative part—the sum of these is the amplitude of relative convergence.

CHAPTER III

METHODS OF DETERMINING THE REFRACTION

In entering upon the practical part of the subject the following subjective and objective methods present themselves for consideration.

1. The acuteness of vision.
2. Scheiner's method.
3. The ophthalmoscope.
   (*a*) The indirect method.
   (*b*) The direct method.
   (*c*) Retinoscopy.

In every case we must proceed in a systematic manner, and before commencing to take the patient's visual acuteness, something may be gained by noticing the general appearance of the patient, the form of the face, head, etc.; thus a flat-looking face is sometimes an indication of hypermetropia; a head elongated in its antero-posterior diameter, with a long face and prominent nose, may indicate myopia. If the two sides of the face are not symmetrical, or if there be some lateral displacement of the nose from the median line, astigmatism may be suspected. We should also notice the shape of the eyes themselves, if large and prominent, or small; in the former case we may suspect myopia, in the latter hypermetropia. Large pupils are suggestive of myopia, and small pupils of

hypermetropia. In high degrees of astigmatism it can sometimes be seen that the curvature of the cornea in one meridian exceeds that of the other. The distance between the eyes should also be noted, as well as the direction of their visual axes.

We next listen to the patient's own statement of the troubles from which he suffers; he may say that he sees distant objects well but has difficulty in reading, especially in the evenings, or that after reading for some time the type becomes indistinct, so that he must rest awhile,—here we suspect hypermetropia; or he may be able to read and do near work, but sees badly at a distance,—then we suspect myopia; or both near and distant vision may be defective,—in this case our first object must be to decide whether the imperfect vision is due to some error of refraction or to some structural change in the eyes themselves; and we possess an extremely simple method by which to differentiate between them, and this method is called the **Pin-hole** test.

Pin-hole Test.—A black diaphragm having a small perforation in its centre (the box of trial glasses usually contains such a diaphragm) is placed quite close to the eye under examination. This perforation gives passage to a small pencil of rays which passes through the axis of the refracting system of the eye, so that the image formed is clearly defined for all distances: if then the pin-hole improve vision, the refractive system is at fault; but if, on the contrary, vision is not improved, then we suspect that the transparency of the media or that the retinal sensi-

bility is defective; thus we possess a very simple and reliable plan, which if used systematically, may save much loss of time. The points to notice when applying this test are, that the illumination is good, and that the pin-hole is immediately in front of the centre of the pupil.

Having then found out that the patient's refraction is defective, we proceed to the first method, the acuteness of vision.

The Acuteness of Vision.—This must not be confused with the refraction, and it is necessary clearly to understand the difference between these two terms. The acuteness of vision is the function of the nervous apparatus of the eye, while the refraction is the function of the dioptric system; so that the acuteness of vision may be normal, even if the refraction be very defective, provided it has been corrected by glasses. The refraction, on the other hand, may be normal, even though the eye is unable to see, as in cases of optic atrophy, etc.

We may define the *acuteness of vision* as that degree of sight which an eye possesses after any error of its refraction has been corrected, and the glasses necessary for this correction are therefore a measure of the error of refraction.

In order to find out the acuteness of vision, we have to determine the smallest retinal image the form of which can be distinguished; it has been discovered by experiments that the smallest distance between two points on the retina which can be separately perceived is 0·00436 mm., about twice the diameter of a single

cone; but it is only at the macula and the part immediately around it, which is the most sensitive part of the retina, that the cones are so close together as ·002 mm.; in the periphery of the field of vision the two points must be further apart to appear distinct.

It is probable that rays from two points must fall upon two different cones in order to be visible as two distinct objects.

The smallest retinal image which can be perceived at the macula corresponds to a visual angle of 1′, so that two stars separated by an angular interval of less than 1′ would produce upon the eye the effect of one star only.

The visual angle has been shown to be an angle included between two lines drawn from the two opposite edges of the object through the nodal point (Figs. 28 and 35).

Fig. 35.

Test-types have been constructed upon these principles for determining the acuteness of vision, Snellen's being those ordinarily used. Every letter is so made that when at its proper distance, each part of it is separated from the other parts by an interval equal

to not less than the arc subtending an angle of 1′ at the nodal point, while the whole letter subtends an angle of 5′.

In order to estimate the refraction by the acuteness of vision, the test object must be placed in a good light, and so far away as to exclude as much as possible the accommodation,—6 metres has been found to be a sufficient distance; rays coming from an object so far off may be assumed to be parallel, and falling on an emmetropic eye at rest, would come to a focus on the retina. The smallest letter which can be seen distinctly at this distance will represent the patient's vision.

Snellen's type consists of rows of letters, each being marked above with the distance in metres at which it should be read. The top letter should be distinct at 60 metres, the next at 36, and each succeeding row at 24, 18, 12, 9, and 6 metres respectively.* The patient placed at six metres should, without any accommodation, be able to read the bottom line with either eye. This is expressed in the form of a fraction, in which the numerator indicates the distance at which it is read, and the denominator the number of the line. We note down the result found for each eye separately: if the bottom line is read, $\frac{6}{6}$ expresses it; if the next, $\frac{6}{9}$; the top, $\frac{6}{60}$, etc.

If our patient, however, be not able even to see

* The set of test-types at the end of the book has an additional line, and is marked 5, so that a greater amount of visual acuteness than $\frac{6}{6}$ can be estimated, and is, of course, recorded $\frac{6}{5}$. Sets of type are now made which go down to $\frac{6}{3}$.

the large letter at the top, we allow him to approach the board, telling him to stop as soon as the letter becomes visible. Supposing he stop at 2 metres from the board, we express that as $\frac{2}{60}$; if he is not able to read it at all, we see how far off he can count fingers. If unable to do this, a lower degree of visual acuteness is found out by determining the ability to distinguish different sorts of light, as to colour, etc. This is called "qualitative perception of light," whereas a still lower degree is to distinguish the difference between light and darkness; this is "quantitative perception of light."

Although the capability of reading the bottom line at 6 metres is the average acuteness of vision, yet it is not the maximum, since many young people will be found who are able to read line six at 7 metres, or even further, in which case their acuteness is $\frac{7}{6}$.

Savages often have an acuteness of vision much in excess of the normal.

Thus we have a standard of normal vision, and a convenient method of expressing it in a numerical manner.

We put our patient then, with his back to the light, in front of the test-types, which must hang well illumined at 6 metres distance, and having armed him with a pair of trial frames, we exclude the left eye from vision by placing in front of it a ground glass disc, and proceed to test the right eye by asking him how much of the type he is able to read; if he read the line marked 6, then his vision is $\frac{6}{6}$ or 1, that is to

say, his distant vision is normal; we may, therefore, assume the absence of *myopia* or *astigmatism;* but he may have *hypermetropia*, and only be able to read $\frac{6}{6}$ by using his accommodation; this we decide by holding a weak convex glass (+ ·5 D.) in front of the eye, when if he still be able to read the same line $\frac{6}{6}$, he has hypermetropia, and the strongest convex glass with which $\frac{6}{6}$ can be read is the measure of the *manifest* hypermetropia; supposing + 1 D. the strongest glass with which $\frac{6}{6}$ can be read, then we record it thus: R. V. $\frac{6}{6}$ Hm. 1 D. = $\frac{6}{6}$.

I say manifest hypermetropia, because in all cases occurring in young people this is not the total hypermetropia; for in these a great part of the error is latent, which can only be discovered by using atropine, or by estimating the refraction by the direct ophthalmoscopic method. Many cases will come before us having two or three dioptres of hypermetropia, who complain that the weakest convex glass impairs distant vision; in these cases the hypermetropia is wholly latent.

We may say, therefore, that a patient who is able to read $\frac{6}{6}$ with one eye, must be—

Emmetropic

or

Hypermetropic in that eye.

If hypermetropic, a part of it is usually *manifest*, as found out by the *strongest* convex glass which does not impair distant vision; or it may be wholly *latent*, when it is necessary to atropise the patient before we can demonstrate it.

Supposing, however, our patient's vision is below the normal, and, instead of reading $\frac{6}{6}$, he is only able to read, say the third line ($\frac{6}{24}$), and that this is blurred with a weak convex glass, he may have—

Myopia,
Astigmatism,
or
Spasm of accommodation (see p. 197).

We try if a weak concave glass helps him; if it does so, the case is one of myopia; and we find the *weakest* concave glass with which he sees best; thus to take an example in which the patient is a myope and sees only $\frac{6}{24}$, but with $-$ 2 D. reads $\frac{6}{6}$; we repeat the examination with the second eye, and record it—

R. V. $\frac{6}{24} - 2$ D. $= \frac{6}{6}$.
L. V. $\frac{6}{24} - 2$ D. $= \frac{6}{6}$.

It our patient is not improved with concave glasses, then we assume that some astigmatism is present, presupposing of course that there is no other cause for bad vision.

To estimate this astigmatism we must call to our aid some of the methods described in the chapter on astigmatism, p. 156, or we may find out the spherical glass with which he is able to see best, then rotate in front of it a weak convex cylindrical glass, starting with its axis vertical; no improvement occurring, we do the same with a weak concave cylinder, starting with its axis horizontal; finding by this plan the glass and its particular axis which gives the best result. It is necessary that the eye be thoroughly under the influence of atropine, in order to enable us to arrive

at definite and reliable results by this method. With practice, one is able in this way to work out simple cases of astigmatism accurately and quickly.

The object in view is always to bring up the vision of each eye as nearly to the normal standard of $\frac{6}{6}$ as possible. Frequently, however, we have to be satisfied with $\frac{6}{9}$ or $\frac{6}{12}$.

But should the case appear to be a difficult one, it is better perhaps for the student not to waste time, but proceed at once to retinoscopy.

When trying the patient at the distant type it is convenient to have two or more sets of letters, so that the type may be changed when the patient gets accustomed to one set.

The near type is chiefly used to estimate the accommodation, by finding out the far and near point at which any particular line is read. Snellen's and Jaeger's are the types most commonly in use, many preferring Jaeger's, owing to the letters being of the ordinary shapes ; but they have the disadvantage that they are not arranged on any scientific plan, but are simply printer's types of various sizes: the set of reading type at the end of the book is so arranged that when held at the distance for which it is marked, each letter subtends an angle of 5′ at the nodal point.

It must, however, be remembered that sentences are an inferior test to letters, many people recognising the words by their general appearance, whereas they may be unable to see distinctly each letter of which the sentence is composed.

Having tested our patient's vision at the distant

type and recorded the result, we place in his hand the reading type, and note the smallest print he is able to read and the distance at which he reads it; first with each eye separately, then with the two together.

In cases of myopia we may thus get a valuable hint as to the amount of the defect: we will take for an example a case in which the patient can read $\frac{6}{24}$ with the right eye; we give him the near type, and if he can read the smallest only by holding it at a *nearer* point than the distance for which it is marked, we note the *greatest* distance at which he is able to read it; if the type marked for 1 metre cannot be read further off than 25 cm., our patient has then most likely myopia of 4 D., because 25 cm. is probably his far point. In this case a glass − 4 D. would give to rays coming from a distant point the same amount of divergence as if they came from 25 cm. ($\frac{100}{25} = 4$).

We try the patient at the distant type with − 4 D.; if he now read $\frac{6}{6}$ the myopia is confirmed, and the weakest glass with which he reads it is the measure of his myopia.

If the patient read $\frac{6}{6}$, but be unable to read the near type except it be held at a further distance than that for which it is marked, the case is one of paralysis of the accommodation, or presbyopia; and as the latter only commences in emmetropia about the age of forty-five, it will be clear according to the age of the patient to which division the case belongs.

As objects seen through convex glasses appear enlarged, and through concave glasses diminished, it follows that these, when placed before the eye, will

exercise the same influence on the size of the retinal image. Now the hypermetropic eye sees objects smaller, and the myopic eye larger than the emmetrope, and if glasses which are to correct the ametropia be placed at the anterior focal point, *i. e.* about 13 mm. in front of the cornea, the retinal image of the ametrope will be of the same size as that of the emmetrope.

Before leaving this subject of the acuteness of vision the following directions may be given:

1st. The test-type must be in a good light; the advantage of artificial illumination is that it is uniform.

2nd. Commence with the right eye, or that which has the best vision, covering up the other with an opaque disc placed in a spectacle frame; do not be contented to allow the patient to close one eye, as he may not do so completely, or he will probably unconsciously slightly diminish the palpebral aperture of the eye under examination, whereby the circles of diffusion may be somewhat diminished and so give misleading results. Neither should he close the eye with his hand, he may look between the fingers, or exercise some pressure, however slight, on the eyeball, which may interfere temporarily with the function of the retina and so cause delay.

3rd. Having noticed what each eye sees without glasses, always begin the examination with *convex* ones, so as to avoid calling the accommodation into action.

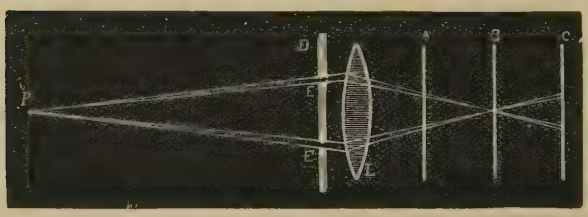
4th. Having recorded the result found for each eye separately, we try the two together, the binocular

visual acuteness being usually slightly greater than that for one eye.

5th. Test the patient with the reading type, noting the farthest point at which the smallest type can be read.

Scheiner's Method.—Although this plan for detecting ametropia is now but little used, it is necessary the student should understand the principles upon which it is based. A diaphragm having two small perforations is placed in front of the eye we wish to examine; the perforations must be so near together that rays passing through them will enter the pupil (Fig 36). The patient is directed to look at a small flame 6 metres off; rays emanate from this flame in all directions, some fall on the diaphragm, the greater number are thus cut off, but a few rays pass through the two openings, and if the eye be adapted for the flame, *i. e.* if it is emmetropic, these two sets of rays will

FIG. 36.*



meet exactly on the retina, forming there one image of the flame (B, Fig. 36); if, however, the eye be

* In the above diagram, P is represented as a near object with rays diverging from it; it should be a distant object with parallel rays.

hypermetropic (with suspended accommodation), then the two sets of rays will reach the retina before meeting, each set forming an image of the flame (A, Fig. 36). The greater the hypermetropia the further apart will the images be formed; these are projected outwards as crossed images, and the patient has therefore crossed diplopia. That convex glass (from our trial box) which, held behind the diaphragm, causes the flame to be seen singly, is a measure of the hypermetropia. If the eye be myopic, then the two sets of rays will have crossed and are diverging when they reach the retina, where two images of the flame are therefore formed (C, Fig. 36). These images are crossed again as they are projected outwards, and having twice crossed, homonymous images are the result. To find the amount of myopia, we have only to find the concave glass which, placed behind the diaphragm, brings the two images into one. To enable us to tell if the images are crossed or homonymous, it is usual to have in front of one of the perforations a piece of coloured glass. We will suppose the diaphragm held so that the two openings are horizontal, that to the patient's right having in front of it a piece of red glass: if only one flame is seen the case is one of emmetropia; if two images of it appear, one white, the other red, with the red to the left of the other, the images are crossed, and the case is one of hypermetropia. If the red appear on the right, then the case is one of myopia. The further apart the images are, the greater is the ametropia.

CHAPTER IV

THE OPHTHALMOSCOPE

The Ophthalmoscope furnishes us with several methods for determining the refraction of the eyes.

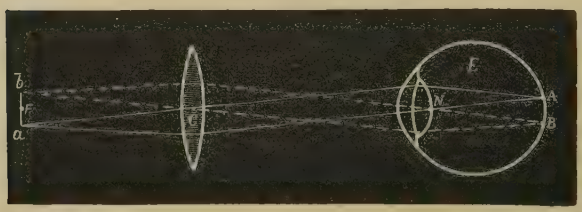
a. The indirect method.

b. The direct method.

c. Retinoscopy.

The Indirect Method.—By the indirect method we obtain an inverted image of the disc by means of a biconvex lens placed in front of the eye. In emmetropia (Fig. 37) rays coming from A emerge from the eye

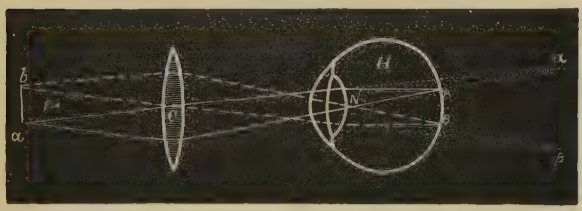
FIG. 37.



parallel, and are focussed by the convex lens at *a*, and rays coming from B are focussed at *b*, so also with rays coming from every part of A B, forming an inverted image of A B at *b a*, situated in the air at the principal focus of the biconvex lens.

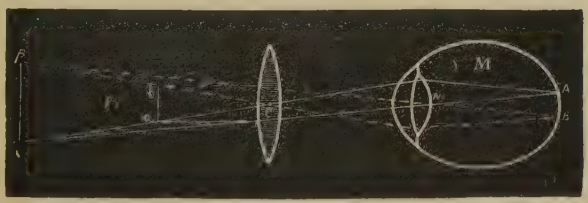
In hypermetropia (Fig. 38) the rays from A emerge

FIG. 38.



divergent, so also of course those from B; if these rays are continued backwards, they will meet behind the eye (at the punctum remotum), and there form an enlarged upright image ($\alpha\,\beta$) of A B; it is of this imaginary projected image that we obtain by the help of the biconvex lens a final inverted image ($b\ a$), situated in front of the lens beyond its principal focus.

FIG. 39.



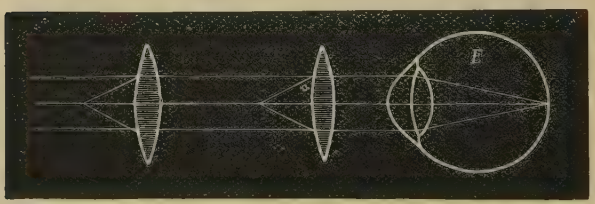
In myopia (Fig. 39) the rays from A and B emerge from the eye convergent, forming an inverted aërial image in front of the eye at $\beta\ a$, its punctum remotum. It is of this image we obtain, with a biconvex lens

placed between it and the eye, a final image (*b a*), situated within the focus of the biconvex lens.

By this method we are able to detect the form of ametropia by the changes which take place in the size and shape of the optic disc, always remembering that the inverted image of the disc, produced by a convex lens at a certain fixed distance from the cornea, is larger in hypermetropia, and smaller in myopia, than in emmetropia. The lens should be held close to the patient's eye, and then gradually withdrawn, while the aërial image of the disc is steadily kept in view; the rapidity with which any increase or decrease takes place in the size of this image gives us an indication of the amount of the refractive error.

If no change take place in the size of the image on thus withdrawing the objective the case is one of emmetropia, because the rays issue from such an eye

FIG. 40.



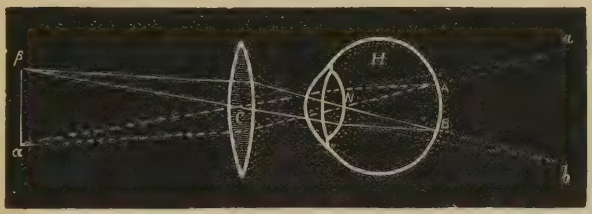
E. Emmetropic eye. Rays issuing parallel, image formed at the principal focus of the lens, no matter at what distance the lens is from the eye.

parallel, and the image formed by the object-glass will always be situated at its principal focus, no matter at what distance the glass is from the observed eye

(Fig. 40). As the distance of the image from the object-lens is always the same, the size of the image will also be the same.

If diminution take place in the size of the image, the case is one of hypermetropia, and the greater the diminution the higher is the hypermetropia.

Fig. 41.



Lens at 4 cm. from the cornea.

Fig. 42.

Lens at 12 cm. from the cornea.

H. Hypermetropic eye. C. The centre of the lens. A B. Image on the retina. *a b*. Projected image. *β a*. The final image formed by the objective.

This change in size may be explained by remembering that in hypermetropia the image of the disc formed by the object-glass is situated beyond its

principal focus, owing to the rays issuing from the eye being divergent; the relative size of the final image β *a* to the object *a b* will therefore vary directly as the length c , and inversely as the length c *a*; so that on withdrawing the lens c from the observed eye, c *a* diminishes and c *a* increases; therefore the ratio of *a* β to *a b* diminishes, *i. e.* the size of the image diminishes. The two diagrams Figs. 41 and 42 show images formed by the object-glass when held at 4 cm. and at 12 cm. from the cornea, the latter image being the smaller.

If the image become larger on withdrawing the object-glass, the case is one of myopia; the greater the increase of the image, the higher the myopia.

This increase in the size of the image can also be explained with the help of mathematics, remembering that in myopia an inverted image is formed in front of the eye (Fig. 45), and it is of this we obtain an image with a convex glass placed between the eye and the inverted image, which we must regard as the object; the object and its image being both on the same side of the lens.

In astigmatism, the disc, instead of appearing round, is frequently oval. If the image of the disc decrease in size in one meridian, while the other remain stationary as the objective is withdrawn from the eye, it is a case of simple hypermetropic astigmatism. If the whole disc decrease in size, one meridian diminishing more than the other, it is compound hypermetropic astigmatism, the meridian being most hypermetropic which diminishes most.

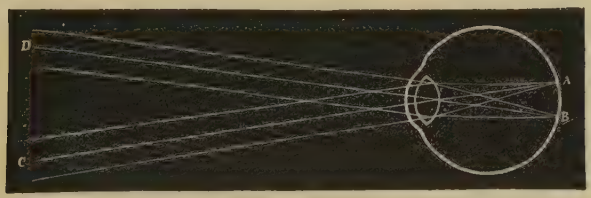
Increase in one meridian, the other remaining stationary, indicates simple myopic astigmatism.

Increase in the size of the disc, but one meridian increasing more than the other, indicates compound myopic astigmatism, that meridian being most myopic which increases most.

If one meridian increase while the other decrease, mixed astigmatism is our diagnosis.

The Large Concave Mirror at a Distance.—If the observer be able to see the disc or some of the vessels with the mirror alone *at a distance* from the patient, the case is one of hypermetropia or myopia. The explanation of this is, that in emmetropia (Fig. 43) the rays which come from the two extremities of the disc (A B) emerge as two sets of parallel rays in the

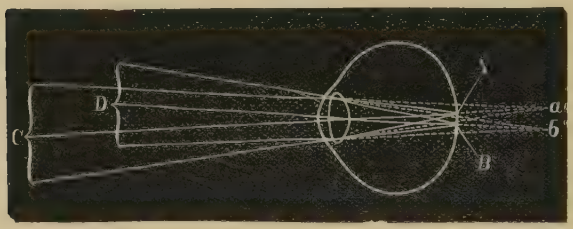
FIG. 43.



same direction as the rays A C, B D, which, having passed through the nodal point, undergo no refraction. These two sets of rays soon diverge, leaving a space between them, so that an observer (unless he be quite close to the observed eye) is able only to bring rays from one point to a focus on his retina; and therefore, at a distance from the eye, the observer sees only a general illumination.

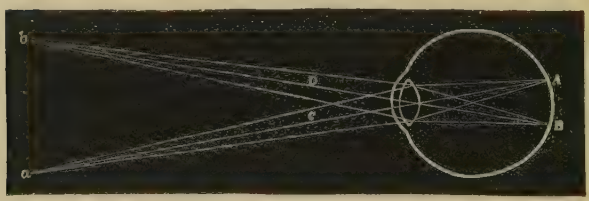
In hypermetropia (Fig. 44) the rays from the two points A B emerge from the eye in two sets of diverging rays, in the same direction as the rays A C, B D, which undergo no refraction. These diverging rays have the appearance of coming from two points (*a b*) behind the eye, where an erect imaginary image is formed.

Fig. 44.



The more the rays diverge on exit, the sooner they will meet when prolonged backwards; and hence the greater the hypermetropia, the nearer will the image be to the nodal point.

Fig. 45.



The observer at a distance sees a clear, erect image which is formed behind the eye.

In myopia (Fig. 45) the rays from the two points

(A B) emerge as two converging sets of rays, which meet at *a b* on their secondary axes, thus forming an inverted image in front of the eye. This image can be distinctly seen by the observer if he be at a sufficient distance from the point, and accommodating for the particular spot at which the aërial image is formed. The higher the myopia, the nearer to the eye will this image be formed.

From the above observations it will be understood that if the observer now move his head from side to side, and the vessels of the disc are seen to move in the same direction, the case will be one of hypermetropia, the image formed being an erect one.

Should the vessels move in the opposite direction to the observer's head the case will be one of myopia, the image being an inverted one formed in the air in front of the eye.

If the vessels of one meridian only are visible, then we have a case of astigmatism, hypermetropic if moving in the same, and myopic if moving in the opposite direction to the observer's head, that meridian being ametropic which is at right angles to the vessels seen.

In mixed astigmatism the vessels of one meridian move against the observer's movements, and those of the other meridian with them: this is difficult to see.

Thus we have obtained an indication of the form of ametropia. We may, however, estimate the amount of error by means of a refracting ophthalmoscope, of which there are many.

The Direct Method.—By the direct examination we

obtain much more important information, not only of a qualitative, but also of a quantitative character.

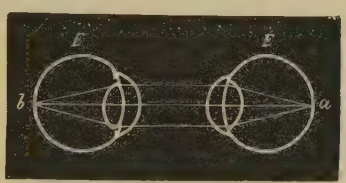
In endeavouring thus to estimate the refraction, it is essential that the accommodation of both the patient and observer be suspended. The observer first corrects any ametropia that he may have, either by having the proper correction in a suitable clip behind the sight-hole of his ophthalmoscope, or he may deduct his own ametropia from the glass which corrects the refraction of the patient and himself in the manner to be presently described. He then sits or stands as he may prefer on the same side as the eye he is about to examine, so as to use his right eye for the patient's right, and his left for the patient's left.

The light is placed on the side to be examined, a little behind and on a level with the patient's ear; then with the mirror held close to the eye to be examined, so that the ophthalmoscope may occupy as nearly as possible the position of the spectacle glass, the observer looks for the disc. We really wish to estimate the refraction at the macula, but to this there are several obstacles: the light falling on this, the most sensitive part of the retina, has a very dazzling unpleasant effect for the patient, and causes the pupil to contract vigorously, the reflex from the cornea and the lens is exactly in the line of vision, and further there are no convenient vessels in this part which we may fix as test objects; whereas the disc is but little sensible to light, and the vessels of this part, as well as the margins of the disc itself, are very convenient for our purpose, and although occasionally the refrac-

tion of the macula and disc are not exactly the same, still practically it is sufficiently accurate to take that of the latter.

To estimate the refraction by the direct method, it is necessary that the patient's accommodation should be relaxed; this will generally be the case when the examination is made in a dark room; or a mydriatic may be used; then, if the observer's own accommodation be suspended, and the image of the disc appear quite clear and distinct, the case is one of emmetropia. This we know, because rays coming from an emmetropic eye (Fig. 46, E) in a state of repose

FIG. 46.

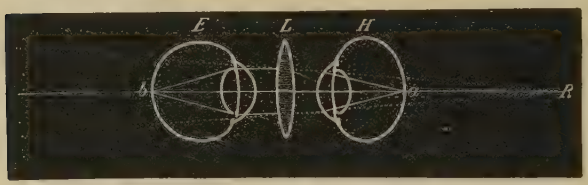


will issue parallel, and the observing eye receiving these rays will, if emmetropic with its accommodation suspended (which often requires great practice), be adapted for parallel rays, so that a clear image of *a* in the observed eye will be formed at *b* on the retina of the observing eye.

Supposing the image does not appear clear and distinct without an effort of accommodation, then we turn the wheel of the ophthalmoscope so as to bring forward convex glasses in front of the observing eye. The *strongest* positive glass with which we are able to

get a perfectly clear image of the disc is a measure of the hypermetropia, because rays coming from *a* (Fig. 47) in the hypermetropic eye (H) issue in a divergent direction as though coming from R, the punctum remotum behind the eye. The convex lens L renders them parallel, and they then focus at *b*, on the retina of the observing emmetropic eye (E).

FIG. 47.

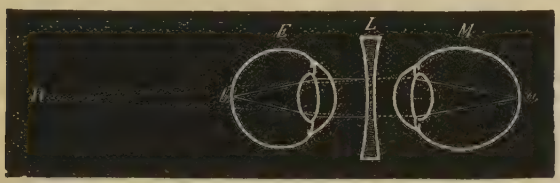


In practice many observers find it difficult or impossible to tell if their own accommodation be completely relaxed, so that if they see clearly the disc of the patient under examination, they do not at once assume that he is emmetropic, but only do so on finding that the weakest convex glass behind the ophthalmoscope impairs the clearness of the image.

If, however, the image of the disc appear indistinct, and the convex glass, instead of rendering the image clearer, have the opposite effect, we must turn the wheel of the ophthalmoscope in the other direction, and so bring forward the concave glasses. The *weakest* with which we can see the details of the fundus clearly is a measure of the myopia, because any stronger glass merely brings into play the accommodation of the observer. Rays from *a* (Fig. 48) leave the myopic

eye (M) so convergent, that they would meet at (R) the punctum remotum. The concave lens L renders them parallel before falling on the relaxed eye (E) of the observer.

Fig. 48.



If the ophthalmoscope is not held very close to the eye, we must deduct from the focal distance of the lens the distance between the cornea and the instrument in hypermetropia, adding them together in myopia (p. 118).

If astigmatism exist, the plan is to find the glass which enables the vertical vessels and lateral sides of the disc to be seen distinctly, and then the glass with which the vessels at right angles are best seen.

Suppose the vertical vessels and lateral sides of the disc appear distinct without any glass, then the horizontal meridian, *i. e.* the meridian at right angles to the vessels clearly seen, is emmetropic; and suppose also that the horizontal vessels with the upper and lower borders of the disc require a convex or concave glass to render them clear and distinct, then the vertical meridian is hypermetropic or myopic, and the case is one of simple hypermetropic or myopic astigmatism.

If both the vertical and horizontal vessels can be

seen with convex glasses, but with a stronger one for the vertical than for the horizontal, then the case is one of compound hypermetropic astigmatism, the horizontal meridian being the more hypermetropic.

If both meridians had required concave glasses, but of different strengths, then the case would be one of compound myopic astigmatism.

If the vertical vessels and the lateral sides of the disc can be seen distinctly through a convex glass, while the horizontal vessels require a concave glass, the case is one of mixed astigmatism, the horizontal meridian being hypermetropic, the vertical meridian myopic.

The essential point to remember is, that the glass with which the vessels in one direction are seen is a measure of the refraction of the meridian at right angles to these vessels.

The estimation of the refraction by the direct ophthalmoscopic method is exceedingly valuable, but requires great practice; some observers find considerable difficulty in relaxing their accommodation completely, even after long practice.

The student should take every opportunity to become thoroughly proficient in estimating the refraction by this method; in fact, every case that is not of an inflammatory character should be examined with the ophthalmoscope, and the refraction as estimated by the direct method recorded as a matter of routine; the ophthalmoscopic examination may conveniently follow the testing of the patient's visual acuity.

In hypermetropia and myopia one is able to estimate the amount of error accurately, and in cases of astigmatism where the chief meridians are horizontal and vertical one can come very near the exact correction, and without necessarily subjecting the patient to the inconvenience of a mydriatic: when the meridians are oblique the estimation is more difficult, because we may find no vessel whose course exactly corresponds with the chief meridians; still the more this method is practised the more accurate will be the results obtained. The correction must always be confirmed by trying the patient at the test types with lenses, making any slight alteration that may be necessary.

It is also an additional advantage that one can estimate the refraction at the same time that one makes an examination of the fundus.

The comparison of the direct and indirect methods of examination is also very useful in astigmatism. If, for instance, the disc is elongated horizontally in the erect, and oval vertically in the inverted image, we know that the curvature of the cornea is greater in the horizontal than in the vertical meridian (see Figs. 86 and 87).

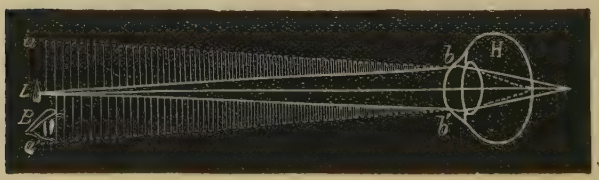
The ametropic observer must always remember, when using the direct method for the estimation of errors of refraction, that he must correct his own defect either by wearing spectacles or by having a suitable glass in a clip behind his ophthalmoscope; he is then in the position of an emmetrope; but, if he prefer it, he may subtract the amount of his own

hypermetropia or myopia from the glass with which he sees clearly the patient's discs. Thus, if the observer have 2 D. of hypermetropia, and require + 3 D. to see the fundus clearly, (+ 3 D.) − (+ 2 D.) = + 1 D., the patient would have 1 D. of hypermetropia; had he required − 2 D., then the observer would have 4 D. of myopia, because (− 2 D.) − (+ 2 D.) = − 4 D.

The same with the myopic observer; if his myopia amount to 3 D., then he will require − 3 D. to see clearly the emmetropic fundus; if he see the disc well without a glass, then the eye under examination has 3 D. of hypermetropia; if he require a + 2 D., then the hypermetropia will be 5 D., and so on.

Ametropia may also be easily recognised in the following manner:—The fundus being illuminated by a mirror about one metre from the patient, if the eye be emmetropic the rays of light will return parallel to one another, and a red reflex can only be obtained when the observing eye is in the path of these rays, that is behind the perforation of the mirror. If hypermetropic the returning rays will diverge (Fig. 49), and

Fig. 49.

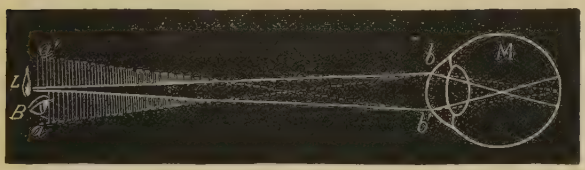


the observer will notice, as he moves his eye (B) from behind the mirror at L (and at right angles to the

visual axis of the patient, who should fix on the centre of the mirror), that the last ray of light (a' b') is seen, or, in other words, the red reflex disappears, on the same side of the pupil as that to which the observer moves his head.

If the eye be myopic the rays will converge, cross, and diverge (Fig. 50); when the error is 1 D.

Fig. 50.



or more, the last ray of light is seen, or the red reflex disappears, on the opposite side of the pupil. A single trial of this will prove its correctness.

The endeavour to estimate the amount of myopia or hypermetropia by measuring the distance between the perforation of the mirror, and the point at which the last ray was seen, has been unsuccessful, owing to the varying size of the pupil.

The ophthalmometer of Javal and Schiötz, and Tweedy's optometer, can, I think, be more conveniently considered when treating of astigmatism.

CHAPTER V

RETINOSCOPY

Retinoscopy, or the shadow test, is deservedly one of the most popular objective methods of estimating the refraction of the eye.

It has the great advantage of being easily learnt, and can be carried out quickly, saving much time in difficult cases of astigmatism; it is especially useful in young children, in amblyopic patients, and in malingerers; besides, it enables very small degrees of astigmatism to be detected which but for this method would probably escape notice. Retinoscopy may be carried out either with a concave or a plane mirror.

Retinoscopy with the Concave Mirror.

If light from the ophthalmoscope lamp be reflected into the eye by means of a concave mirror, at a distance of a metre or so, an observer looking through the sight-hole of the mirror will notice the ordinary red fundus reflex; on slightly rotating the mirror the illuminated area of the pupil may disappear (or, what may be more easily seen, the edge of the shadow bounding this illuminated area may appear), on the same side as the rotation or in the opposite direction,

according to the refraction of the eye under observation: thus if the mirror be rotated to the right, and the edge of the shadow move across the pupil also to the right, *i. e.* in the same direction as the rotation of the mirror, the case is one of myopia; whereas if the shadow had moved in the opposite direction to the mirror, the case would be one of hypermetropia.

This method of employing retinoscopy is so simple that a few practical trials will suffice to make it understood, although, of course, as in all other manipulations some little practice is required in giving to the mirror the necessary movements, and enabling one to appreciate what is seen.

A mydriatic is not absolutely essential; still, when we have to examine young people and children, the use of atropine is most certainly advisable. In the first place, the dilatation of the pupil renders our examination so much easier; and secondly, atropine enables us to arrive at a more accurate estimation by thoroughly paralysing the accommodation: for although the examination take place in a dark room, and with the patient looking into distance, it must be remembered that there is often (especially in the case of children) some accommodation still in force: or there may be spasm of the ciliary muscle.

In persons over the age of twenty, atropine is not usually employed owing to the great discomfort entailed by its paralysing effects on the ciliary muscles, which lasts for seven or eight days, and because the use of this drug has occasionally produced glaucoma in people beyond middle life; we may, however, wish

to dilate the pupils with a mydriatic that acts fully and quickly, and whose effects last but a short time. The most convenient combination for this purpose is—

℞ Homatropinæ Hydrobromatis, gr. iv;
Cocainæ Hydrochloratis, gr. x;
Acidi Salicylici, gr. j;
Aq. Destillatæ, ʒj.
Ft. guttæ.

A drop or two of this solution applied two or three times at intervals of ten minutes produces rapidly a maximum dilatation of the pupil, which passes off in about twelve hours.

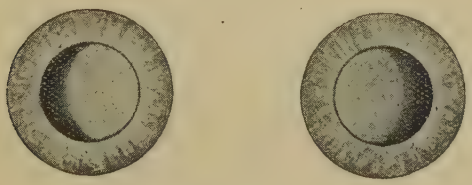
Another great advantage of a mydriatic is that the refraction of the macula can be measured, whereas when the pupil is not dilated we have to be satisfied with the refraction at the optic discs, which may occasionally vary considerably from that found at the macula: the estimation of the refraction at the macula constitutes one of the chief advantages that retinoscopy possesses over the measurement obtained by the direct method.

To examine the patient, then, we dilate his pupils, and seat him in a dark room, with a lamp placed over his head, so far back that it throws no direct rays upon his face; the lamp in this position will not require moving during the examination of either eye. The observer takes up a position about 120 cm. in front of the patient, and directing him to look at the perforation in the concave mirror (which should have a focus of 25 cm.), the observer will be enabled to reflect the light along the visual axis, and thus obtain the ordinary red fundus reflex.

If a mydriatic has not been used, this procedure will cause the pupil so to contract, that it will be difficult to see the shadows; and in that case the observer must make the patient look a little inwards, so that the light may be reflected along the optic axis. If we now rotate the mirror slightly from side to side on its vertical axis, we see a shadow come out from behind the pupil, moving horizontally across the illuminated part. The edge of this shadow may be linear or somewhat crescentic: its direction may vary, being either vertical or oblique; if oblique, then we know at once that astigmatism is present. The shadow moves either in the same or the opposite direction to the mirror, so that when the latter is tilted to the right the shadow may come from the left, or *vice versâ*.

Thus, assuming the shadow's edge to be vertical (Fig. 51), if it move with the mirror the case is one of myopia; but if it move against or in the opposite direction to the mirror, the case is either one of hypermetropia, emmetropia, or low myopia.

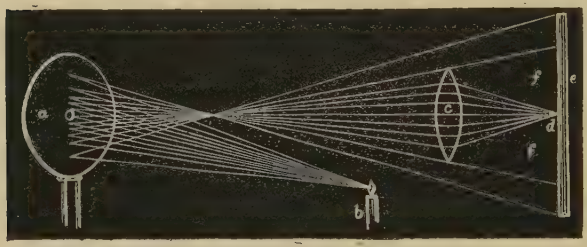
FIG. 51.



What is this shadow whose edge we see? How and where is it formed? and what influences its movements and clearness?

To enable us to answer these questions, we will place before a screen a convex lens, at such a distance

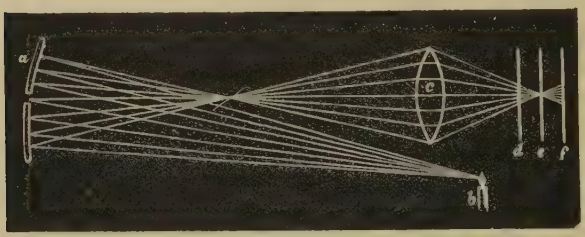
Fig. 52.



a. The concave mirror. *b*. The candle. *c*. The lens. *d*. Small image of candle formed on screen. *e*. The screen. *f*. Dark shadow around.

from it that converging rays from a concave mirror, having crossed and become divergent, are brought to an exact focus, and there is then formed a very small, erect, well-defined image on the screen of the lamp

Fig. 53.



At *e* a small image of the candle is formed; at *d* and *f*, circles of diffusion.

from which the concave mirror received its rays; erect, because it has suffered two inversions.

This image of the lamp is surrounded by a sharply defined and dense shadow.

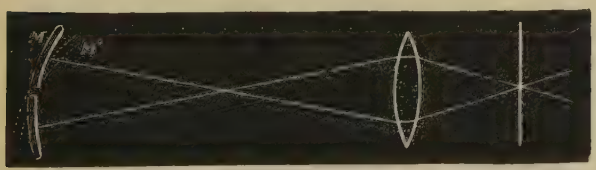
If we move the lens nearer to, or farther from the screen, the area of light becomes larger, and the illumination feebler.

The mirror being rotated on its vertical axis, the image of the candle, with the surrounding shadow, will always be found to move in the opposite direction to the mirror, whatever be the distance of the lens from the screen.

This is exactly what takes place in the eye, of which our screen and lens are a representation.

It may therefore be stated that the illumination and shadows which we see are an enlarged image of the lamp with the surrounding shadow, brought more or less to a focus on the retina according to the refraction of the eye. They always move against the

FIG. 54.



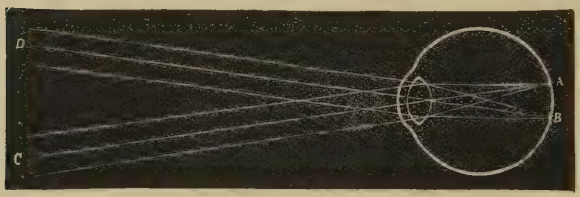
M. The mirror. M′. The mirror after rotation. The extremities of the dotted line have moved in the opposite direction to the rotation of the mirror.

mirror: but as these movements are seen through the transparent media of the eye, and thereby undergo refraction, the "apparent" may differ from the "real"

movements. The image we see of the lamp, and its surrounding shadow, are formed in the same manner as all other images; and it may be well to repeat here what has already been said with regard to the formation of these images.

In emmetropia the image is formed at infinity; thus

Fig. 55.

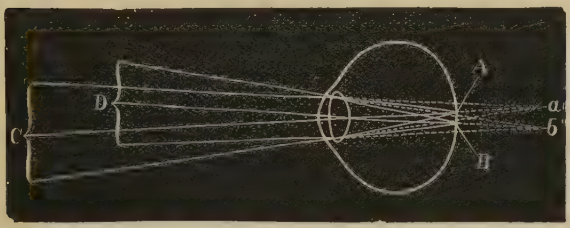


the rays which come from the two extremities, A, B, emerge as two sets of parallel rays, in the same direction as the rays A C, B D; which, having passed through the nodal point, undergo no refraction. These two sets of rays soon diverge, leaving a space between them, so that an observer, unless he be quite close to the observed eye, is unable to bring these rays to a focus on his retina; and, therefore, at a distance from the eye the observer sees only a diffused and blurred image.

In hypermetropia the image is formed behind the eye; thus the rays from the two points A, B (Fig. 56) emerge from the eye in two sets of diverging rays, in the same direction as the rays A C, B D, which undergo no refraction. These diverging rays have the appearance of coming from two points *a*, *b*, behind the eye, where an erect image is formed, *a b*.

The more the rays diverge on exit, the sooner they will meet when prolonged backwards; and hence the

Fig. 56.

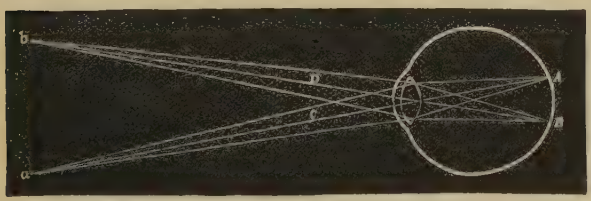


greater the hypermetropia, the nearer will the image be to the nodal point.

The observer, at a distance, sees a clear, erect image, which is formed behind the eye.

In myopia an inverted image is formed in the air in front of the eye; thus the rays from the two points A, B, emerge as two converging sets of rays, which

Fig. 57.



meet at *a*, *b*, on their secondary axes, thus forming an inverted image in front of the eye. This image can be distinctly seen by the observer if he be at a sufficient distance from the point, and accommodating

for the particular spot at which the aërial image is formed.

We have already seen that the real movements of the shadows on the retina are against the mirror.

In hypermetropia the final image of the candle and its surrounding shadow, produced by the concave mirror, is an erect one formed behind the eye, and as it is viewed through the dioptric system of the eye, it therefore moves against the mirror.

In myopia the final image is an inverted one, projected forwards. This, therefore, moves with the mirror, it having undergone one more inversion.

To this rule, that in myopia the image moves with the concave mirror, there are two exceptions:

1st. If the observer be nearer the patient than his far point, but not within the focal distance of the mirror, the image will move against the mirror. This is frequently the case in low degrees of myopia, where the patient's far point is beyond 120 cm.

2nd. If the observer be within the focal distance of the mirror, although beyond the far point of the patient, the image will in this case also move against the mirror. This source of error can always be avoided by using a concave mirror of 25 cm. focus, and keeping 120 cm. from the patient.

Therefore, if the image move with the mirror, the case is certainly one of myopia. If it move against the mirror, it is most likely one of hypermetropia; but it may be emmetropia, or a very low degree of myopia.

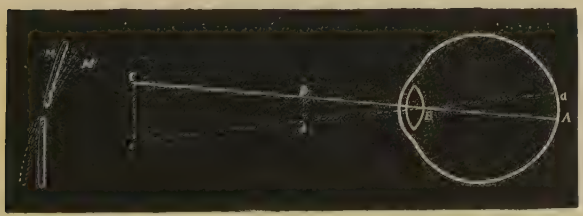
The movements tell us the form of ametropia we

have to deal with. The extent of the movements on rotation of the mirror, the clearness of the image, and the brightness of its edge, enable us to judge approximately the amount of ametropia to be corrected; some practice, however, is required before we can form an opinion with anything like accuracy.

The extent and rate of movement is always in inverse proportion to the ametropia; the greater the error of refraction, the less the movement, and the slower does it take place. This may be explained in the following way:

Suppose A to be the image of a luminous point formed on the retina, and that a line be drawn from A through the nodal point B to C. Now, if the case be one of myopia (Fig. 58), an inverted projected image of A is formed somewhere on this line, say at C. The higher the myopia, the nearer to the nodal point will this image be; and hence we may suppose it formed as near as D. If the mirror be now rotated, so that it

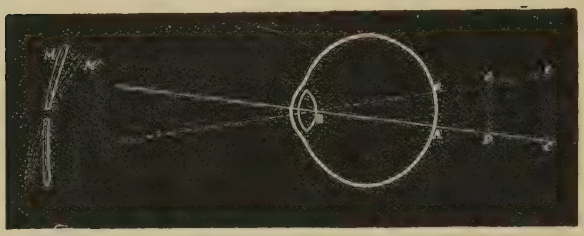
FIG. 58.



take up the position of the dotted line M′, C will have moved to *c*, and D to *d*; hence it is clear that C has made a greater movement than D.

Had the case been one of hypermetropia (Fig. 59), the image would have been projected backwards, and,

Fig. 59.



as in myopia, the higher the degree of error the nearer to the nodal point is the image formed.

In this case the line from the nodal point B to A is prolonged backwards, and the image of the luminous point in a low degree of hypermetropia is formed say at C, and in a higher degree say at D. On moving the mirror into the position of the dotted line M′, C moves to *c*, and D to *d*; hence it is clear that C has made a greater movement than D.

Therefore, as the ametropia increases, the extent of the movement of the image decreases. The clearness of the image and the brightness of its edge decrease as the ametropia increases.

It was shown in Fig. 53 that on placing before a screen a convex lens, at such a distance that converging rays from a concave mirror, having crossed and become divergent, are brought to an exact focus, forming a small erect, well-defined image on the screen of the lamp from which the concave mirror received its rays, on moving the lens nearer

to or farther from the screen, the larger becomes the area of light, and the feebler the illumination, owing to the circle of diffusion formed on the screen.

Therefore, in the case of the eye, the greater the ametropia, the larger is the circle of diffusion and the weaker the illumination, so that the image we see is less bright and its edge less distinct.

It is, therefore, in the lower degrees of ametropia that the brightest and best defined shadows are seen.

Having thus answered the questions concerning the shadows which we see in retinoscopy, we are in a position to pursue further the practical working of the subject, with special reference to the correction of any existing error of refraction by glasses.

The patient, then, being seated in the dark room, the pupils dilated, and the lamp over his head, as before described, we take up our position 120 cm. in front, with a concave mirror of 25 cm. focus (a Galezowski mirror is the one commonly used, and is found convenient). The patient is then directed to look at the centre of the mirror, so that the light from the lamp may be reflected along the visual axis. On looking through the perforation of the mirror we get the ordinary fundus reflex, bright if the patient be emmetropic, less so if he be ametropic; and the greater the ametropia, the less bright will the fundus reflex be. We now rotate the mirror on its vertical axis to the right; if a vertical shadow come across the pupil from the patient's right, *i. e.* in the same direction as the movement of the mirror, or, what is the same thing, if the shadow move in the same

direction as the circle of light on the patient's face, the case is one of myopia. Should the edge of the image appear well defined and move quickly, in addition to a bright fundus reflex, we infer that the myopia is of low degree, and proceed to correct it.

Each eye must, of course, be tried separately.

The patient having put on a pair of trial spectacle-frames, we place a weak concave glass, say — 1 D., before the eye we are about to correct. If the image still move with the mirror, we place in the frame — 1·5 D., then — 2 D., and so on, until we find the point at which no distinct shadow can be seen. Supposing this to be — 2 D., and that on trying — 2·5 D. the image move against the mirror, — 2 D. is assumed to be the correcting glass. This, however, will be found not to be the full correction of the myopia, because the observer being 120 cm. away, when the patient's far point approaches that distance the observer will be unable to distinguish the movements of the shadow; and when the far point of the observed, though not situated at infinity, is still at a greater distance than the observer, the shadow moves in the opposite direction. Hence it is customary in cases of myopia to add on — 1 D. to the correcting lens, and this would give us — 3 D. as the proper glass for our case.

In correcting myopia it is a convenient and reliable plan to stop at the weakest concave glass which makes the image move against the mirror, and put that down as the correcting lens.

When the myopia is of high degree, and a strong

concave glass has to be used for its correction, the light reflected from the mirror is so spread out by the concave glass that fewer rays pass into the eye, and therefore the illumination is not so good as in other states of refraction, and the examination becomes more difficult.

Had we obtained a reverse shadow we should then try convex glasses, when if + ·5 D. neutralised it, we should assume the case to have been one of low myopia. Had it required + 1 D., then it would be one of emmetropia; above this, hypermetropia. We proceed exactly as before, putting up stronger and stronger lenses, until we are unable to make out the movements of the image. This is assumed to be the correcting glass; and just as in the above case the myopia was under-corrected, so in this the hypermetropia is slightly over-corrected, and hence it is usual to deduct from this glass + 1 D.; or we may stop at the strongest convex glass with which we still get a reverse shadow.

To sum up, therefore, if the shadow move with the mirror, it is a case of "myopia;" if against, it may be weak myopia if + ·5 D. cause the image to move with the mirror; emmetropia if + 1 D. neutralises it; hypermetropia if a stronger glass is required.

The points to be observed are—(1) the direction of the movement of the image, as indicating the kind of ametropia: (2) the rate and amount of movement, (3) the brightness of the edge of the image, and (4) the amount of fundus reflex all indicate the degree of ametropia.

We have taken notice only of the horizontal axis, but any other meridian will, of course, do equally well, if the case be one of hypermetropia or myopia simply. If, however, the case be one of astigmatism, then the refraction of the two chief meridians will differ.

In astigmatism, the image of the flame of the candle formed on the retina is distorted so as to be more or less of an oval form, according to the position of the retina and the maximum and minimum curvatures of the cornea.

In the normal eye the focus of the vertical meridian of the cornea is slightly shorter than that of the horizontal. So long as no impairment of vision occurs, the eye is said to be normal, and we speak of the condition as normal regular astigmatism. When, however, the acuteness of vision is diminished, then astigmatism is said to exist.

Parallel rays, passing through a convex spherical lens (disregarding some slight irregularities due to aberration), form a cone, any section of which, perpendicular to its axis, will be a circle. The size of the circle depends upon the distance of the point at which the lens is from its focus. If the cone be divided beyond the focus as in myopia, the rays having crossed and become divergent, a circle of diffusion is formed on the retina. In hypermetropia the cone is divided before having come to a focus, and thus forms a diffusion circle. But in astigmatism the divided cone is circular only at one point, No. 4 in Figs. 76 and 77. To explain this, we place in

front of the convex spherical glass, a weak convex cylindrical glass, with its axis horizontal. The result of this is, that parallel rays passing through this combination do not form a circular cone, because the rays which pass through the vertical meridian, come to a focus before those passing through the horizontal, as shown in Fig. 76.

The rays being divided at 1, an oblate oval is formed; at 2, a horizontal straight line, the vertical rays having come to a focus; at 3, 4, 5, the vertical rays have crossed and are diverging, and the horizontal rays are approaching; at 4, a circle is formed; at 6, a vertical straight line, the horizontal rays having met while the vertical are still diverging; a large prolate ellipse is formed at 7.

So that, in astigmatism, the image on the retina may be more or less of an oval; instead of being either a small well-defined image of the candle, or a circle of diffusion, as in the case of emmetropia, myopia, or hypermetropia. This oval may have its edges horizontal and vertical; frequently, however, they are more or less oblique, as shown in the following figures (Fig. 60).

The oblique movements of the shadows are independent of the direction in which the mirror is rotated.

This obliquity is produced thus (Fig. 61):—if we cut a circular opening in a piece of cardboard to represent the pupil, and then place behind it an oval piece of card which is to represent the shadow, so that that part of its edge which occupies the pupil has an

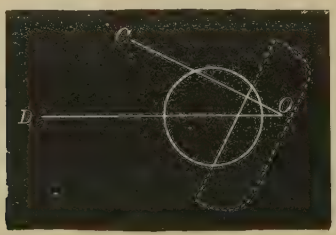
oblique position, then on moving the card across in the direction o D, it has the appearance of moving in

Fig. 60.

Oblique shadows in astigmatism.

the direction o C, at right angles to the edge of the card. Hence the direction of the shadow's movement is deceiving, and its oblique edge is due to the fact that only that edge which coincides in direction with one of the principal meridians is seen well defined by the observer. Therefore the apparent movements correspond with the edge of the shadow.

Fig. 61.



The same takes place in astigmatism, the two chief meridians of which are parallel and perpendicular to the edge of the shadow. In retinoscopy, therefore,

when the edge of the image is oblique, we know at once that the case is one of astigmatism.

Another characteristic appearance that will be sometimes met with in astigmatism, is, that the fundus illumination may assume a band-like shape something like Fig. 62; and on tilting the mirror on an axis parallel to this band, a dark shadow will appear to

Fig. 62.

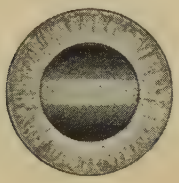


Fig. 63.

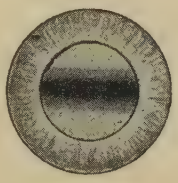


come from both edges of the pupil at once, uniting in the centre to form a black band, leaving the upper and lower part of the fundus illuminated as shown in Fig. 63. This band is parallel with one of the chief meridians, and indicates the point of exact neutralisation of the meridian at right angles to it. The effect is due to the retinal images being now in the form of a line (see Figs. 76 and 77, ii and vi).

Supposing we take a case in which the meridians are horizontal and vertical, we judge if one shadow be more distinct or quicker in its movements than the other, though it is not always easy to recognise the presence of astigmatism at once, so that it is necessary to commence to correct one meridian. If the shadow move against in all meridians, we first take the vertical, and put up in front of the patient, in the spectacle-frame,

convex spherical glasses, until we find the *strongest* with which the shadow still moves against the mirror. We put this down as the correcting-glass for the vertical meridian, and let us suppose that glass to be + 2 D. We next take notice of the horizontal meridian, and if + 2 D. is also the highest glass with which we still get a reverse shadow, then of course we know the case is one of simple hypermetropia. But supposing the highest convex glass had been + 4 D., we indicate it conveniently thus:

$$-\Big|\begin{matrix}+2\text{ D.}\\ -+4\text{ D.}\end{matrix}$$

The case is one of compound hypermetropic astigmatism, and should require for its correction + 2 D. sphere combined with + 2 D. cylinder axis vertical.

We will take another case—that in which the vertical meridian requires − 2 D. to give a reverse shadow, while in the horizontal meridian + 2 D. is found to be the highest convex glass with which we still obtain a reverse shadow. Here we have a case of mixed astigmatism, which can be corrected in either of the three following ways:

1st. − 2 D. cylinder axis horizontal combined with + 2 D. cylinder axis vertical; this is a plan seldom used, and is not so easy to work with as a sphere and a cylinder.

2nd. − 2 D. sphere combined with + 4 D. cylinder axis vertical, or

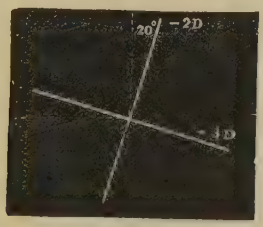
3rd. + 2 D. sphere combined with − 4 D. cylinder axis horizontal. This last is perhaps the preferable

plan. Opticians like working − cylinders on to + spheres, rather than + cylinders upon − spheres.

Supposing the axis of the shadow to be oblique (Fig. 60), we know at once that astigmatism exists, and we proceed to correct each meridian separately, moving the mirror at right angles to the edge of the shadow, not horizontally and vertically. We judge of the amount of obliquity by the eye, and can frequently tell within a few degrees. If the vertical meridian be 20° out, and require for its correction — 2 D., and the axis at right angles to this (which will therefore be at 110°) require — 3 D., we express it as Fig. 64, and correct it with sphere — 2 D. combined with cylinder — 1 D. axis 20°: this case is one of compound myopic astigmatism.

Often one is able to put up the cylinder in the spectacle-frame with the exact degree of obliquity.

Fig. 64.



Having found the glasses which correct the two meridians, we put up the combination in a spectacle trial frame, and if we now get only a slightly reversed shadow in every direction, the glasses are assumed to be the right ones, and we proceed to confirm it by

trying the patient at the distant type, making any slight alterations that may be necessary.

I cannot too strongly recommend the use of sulphate of atropine in solution, gr. iv to ℥j, frequently dropped into the eyes for three days prior to the examination, so as thoroughly to relax the accommodation. It can be used without fear, and without a great amount of inconvenience in most young people under twenty years of age. I have worked out a great many cases of astigmatism, and feel more and more the necessity of using this drug to enable one to arrive at exact results. I might say that I have seldom seen a young person whose astigmatism has been worked out without atropine wearing the right correction; and the inconvenience entailed upon the patient for two weeks by its use is not to be compared to the trouble and asthenopia from which he is so liable to suffer if the glasses worn are not the proper ones.

Retinoscopy with the Plane Mirror.

Many observers prefer to use the plane mirror, they consider that the shadows are more easily seen, and that the results obtained are more exact than those found with the concave mirror. I now use the plane mirror entirely, and find it works well; much depends, however, upon practice and the mirror one is accustomed to.

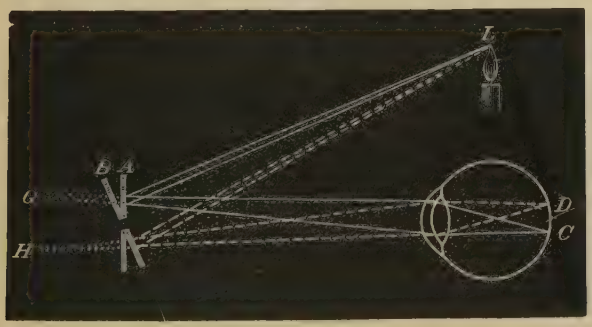
The essential point to remember is that the movements of the shadows with the plane mirror are the reverse of those which have been described under the concave mirror, viz. the shadows move in the same

direction as the movement of the mirror in hypermetropia, and in the opposite direction in myopia.

The explanation is that the concave mirror produces a real image of the light in front of it, between the mirror and the patient; this image becomes the object for the observed eye, and therefore the light on the retina moves in the opposite direction to the mirror. The image from the plane mirror is a virtual one situated behind the mirror, so that the real movement of the light on the retina is with the mirror.

The following diagram (Fig. 65) may help to make this clear.

FIG. 65.



Rays of light from L fall on the plane mirror A, and are reflected as divergent rays into the eye as if coming from point G behind the mirror; these rays focus on the retina at C. On tilting the mirror into position B, the rays from L diverge from the mirror (as if coming from H) and focus at D; therefore the real movement of the light on the retina is with the mirror.

Dr. Jackson of Philadelphia has proposed a further modification; he uses a plane mirror, and thus describes the practical application of the method.

"*Simple myopia.*—Rays of light from any given point of the retina emerge from the myopic eye convergent, and meet at the point in front of the eye for which the eye is optically adjusted. The accommodation being in abeyance, this will be the far point of distinct vision. So that there is formed at the far point of the myopic eye an inverted image of the retina. If now the eye of the observer be placed between the patient's eye and its far point, there will be seen an erect image of the patient's retina; but if the observer view the patient's eye from somewhere beyond its far point, he will see not an erect image, but the inverted image formed at the far point. In the first case the boundary of light and shade which marks the border of the retinal area will appear to move with the facial area; in the second case, against it. In practice the surgeon begins the examination somewhat more distant from the patient than the far point of the eye under examination. Then he slowly approaches the patient, all the while watching the apparent movement of the retinal area produced by slightly rotating the mirror from side to side about its axis.

"As long as this apparent movement is opposed to that of the facial area, the surgeon knows he is watching the inverted image beyond the patient's far point. Presently, however, the direction of the movement of the retinal area cannot be distinguished, the far point

has now been reached; and coming still closer the apparent movement again becomes distinct, but is seen to correspond in direction with the real movement, the far point has now been passed, and the patient's retina is being viewed in the erect image. By noting the point at which this reversal occurs, the surgeon notes the far point of the eye under observation; by measuring the distance from this point of reversal to the eye, he measures the distance from the patient to his far point of distinct vision; and the reciprocal of this distance, of course, expresses the degree of his myopia. Thus, supposing the point of reversal to be one fourth of a metre in front of the eye, one divided by one fourth equals four, the number of dioptres of myopia present.

"Theoretically, the method as now described is complete, but for convenience and accuracy in its application, one or two other points must be attended to. When the observer's eye has come quite close to the patient's, say to within one eighth of a metre, and the inverted image is still seen between them, it is best to place a concave lens (— 8 D.) before the patient's eye, and then to estimate the amount of myopia remaining uncorrected; and by adding it to the amount which the lens used has corrected, determining the total myopia present. When the observer has approached so near the inverted image that it lies closer to his eye than his near point of distinct vision, he can no longer see that image distinctly. Still he can distinguish in which direction the retinal area appears to move, until he approaches somewhat

nearer to the image, when the circles of diffusion upon his own retina become so large that the retinal area of light, seen in the patient's pupil, seems very diffuse and faint, and the direction of its apparent movement uncertain. Because of this there is great practical difficulty in determining exactly where the point of reversal is situated. Now it is evident that if the point of reversal is within a few inches of the eye, an error of two or three inches as to its position entails an error of some dioptres in the amount of myopia present. Therefore, when by the method above described the degree of myopia has been approximately ascertained, place before the patient's eye a concave lens strong enough to remove the point of reversal a metre or more from the eye. At such a distance, an error of two or three inches as to the position of the point of reversal is of no consequence; and an accurate determination of the remaining, and hence of the total myopia can readily be made. Having determined the amount of myopia present, the surgeon will of course be guided by the rules he would follow had the myopia been measured by any other method.

"*Hypermetropia.*—On viewing the fundus reflex it is found that at all distances the erect image is seen, and the retinal area appears to move with the facial area. Place before the patient's eye a convex lens strong enough to over-correct the hypermetropia. Then, by the method given above, determine the degree of myopia so produced. Deduct this amount of myopia from the strength of the convex lens used;

and the remainder will express the degree of hypermetropia present. Suppose, for example, the hypermetropia amounts to four dioptres. Placing a five-dioptre convex lens before the eye, it is found that one dioptre of myopia is produced, the point of reversal being at one metre. Then five, *minus* one, equals four, which expresses in dioptres the amount of hypermetropia present. Should it be found that the + 5 D. lens leaves the eye hypermetropic, so that the erect image is seen at all distances, replace it by a + 10 D., and proceed as before. As in myopia, however, the final accurate determination should be made at a distance of not less than one metre. It may be noticed that low degrees of myopia may be measured without the use of any lens, but that to determine the degree of hypermetropia present a convex lens is always necessary.

"*Emmetropia* is determined by the method for measuring hypermetropia. The convex lens being placed before the eye, the resulting myopia is found to equal exactly the strength of the lens in use.

"*Regular astigmatism.*—In applying the test to the measurement of regular astigmatism, instead of rotating the mirror about any axis, vertical, horizontal, or oblique, as may be done when the curvature of the cornea is the same in all directions, it is rotated about axes perpendicular to the directions of the principal meridians of curvature, and the point of reversal thus found for each principal meridian. To determine the direction of these principal meridians, the eye, if not previously so, should be rendered

myopic in all meridians, and then viewed from different distances. It will then be found that at certain points the fundus reflex takes the shape of a more or less distinct band of light stretching across the pupil, while on one or both sides of it may be seen a shaded area, the 'somewhat linear shadow' of Bowman. This band of light is very readily moved in a direction perpendicular to its length, but in the direction of its length cannot be made to move at all. The point where this appearance is presented is the point of reversal for that principal meridian of the cornea whose direction coincides with the length of the band. The other principal meridian is, of course, at right angles to this, and the observer, by placing his eye at its point of reversal, will be in position to see a similar band extending in a direction perpendicular to that of the band first observed. This use of the shadow test may be made clearer by the consideration of what occurs in a particular case. Suppose the patient's cornea to have such a curvature as to cause in the horizontal meridian (axis vertical) a hypermetropia of four dioptres, and in the vertical meridian (axis horizontal) a myopia of one dioptre. Place before the eye a + 5 D. spherical lens. On approaching it from a distance, it is found that the retinal area moves against the facial area in all directions. But as the distance of one metre is approached, it is noticed that the retinal area takes the form of a horizontal band, readily moveable upward or downward, but difficult to move to the right or left; and when the point of one metre is

reached, all movement to the right or left ceases, and the band is more distinct. Going still closer, the point of reversal for the horizontal meridian being passed, movement to the right or left reappears, but it is now with the facial area. The movement upward or downward is still against that of the facial area. As the patient is still approached, the appearance of a horizontal band fades out, and presently is replaced by that of a vertical band. The vertical band moves readily to the right or left, but less distinctly upward or downward, and at one sixth of a metre all vertical motion is lost. This is the point of reversal for the vertical meridian. On approaching still closer, vertical movement reappears, but like the horizontal movement it is now with the facial area, not against it. Thus it is found that for the horizontal meridian the point of reversal is one metre distant from the eye, and that for the vertical meridian the point of reversal is one sixth metre distant. That is, the use of the convex lens has made the eye myopic in the one meridian one dioptre, in the other meridian six dioptres; and by taking into account the effect of the spherical lens used, the mixed astigmatism is seen to be what we supposed it. But for accurate work, as in simple myopia and hypermetropia, the degree of ametropia for each meridian should be finally determined with such a lens before the eye as would place the point of reversal, for that meridian, one metre or more distant."

A few cases from my note-book will do more than

any description to elucidate the subject of retinoscopy as carried out with the concave mirror.

Case 1. *Spasm of Ciliary Muscle.*—Boy aged 11 years.

$$\text{R.V.}\tfrac{6}{12}-1\text{ D.}=\tfrac{6}{6}.$$
$$\text{L.V.}\tfrac{6}{12}-1\text{ D.}=\tfrac{6}{6}.$$

Bright fundus reflex, shadow moves with the mirror, but with − ·5 D. a reverse shadow is seen. The case, therefore, looks like one of weak myopia. Ordered guttæ atropiæ, gr. iv to ʒj three times a day; on the third day, with retinoscopy, + 1·5 D. still gives an opposite shadow. On trying the patient at the distant type with + 1·5 D. both eyes read $\frac{6}{6}$ well. This, therefore, was a case of hypermetropia simulating weak myopia, due to ciliary spasm: such cases are not rare.

Case 2. *Hypermetropia.*—Girl aged 13, suffering from "tinea tarsi."

$$\text{R.V.}\tfrac{6}{6}\text{ Hm. 1 D.}=\tfrac{6}{6}.$$
$$\text{L.V.}\tfrac{6}{6}\text{ Hm. 1 D.}=\tfrac{6}{6}.$$

Guttæ atropiæ sulphatis, gr. iv to ʒj. Fundus reflex moderate; a reverse shadow is seen moving somewhat slowly. On trying + 2 D., shadows become much more distinct and the movement quicker; + 4 D. is found to be the strongest glass with which we still get a reverse shadow. With + 4 D. $\frac{6}{6}$ was read, but with no stronger glass; this, therefore, is the measure of the patient's total hypermetropia.

Case 3. *Hypermetropic Astigmatism.*—Young man aged 20.

$$\text{R.V.}\tfrac{6}{24}\text{ Hm. 4 D.}=\tfrac{6}{9}.$$
$$\text{L.V.}\tfrac{6}{24}\text{ Hm. 4 D.}=\tfrac{6}{12}.$$

Under atropine, right eye at distant type sees only $\frac{6}{60}$. Fundus reflex very dull, movements of shadow slow and against the mirror. On putting up + 5 D. the reflex is much brighter, the edge of shadow distinct, and its movements quicker. We try + 6, 7, 8, 9, and the last gives a shadow moving with the mirror. + 8 D. is the highest, which still leaves the shadow moving against. On trying the eye at the distant type, $\frac{6}{9}$ and four letters of $\frac{6}{6}$ are at once read. No alteration in the glass improves sight.

Left eye: fundus reflex and movements as in right. We commence by trying + 8 D., which we found the other eye required. In the vertical meridian the movement is against the mirror, while + 9 D. causes it to move with it. In the horizontal meridian with + 8 D. the shadow moves with the mirror, and + 7 D. causes it to move against. We express it thus:

$$-\Big|\begin{matrix}+8\text{ D.}\\ -+7\text{ D.}\end{matrix};$$

and on trying the combination at the distant type,

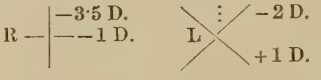
$$\frac{+7\text{ D. sp.}}{+1\text{ D. cylinder axis horizontal,}}$$

the patient is able to read $\frac{6}{9}$; and on decreasing the sphere from 7 D. to 6·5 D., $\frac{6}{6}$ is read, so that the proper correction for this eye is—

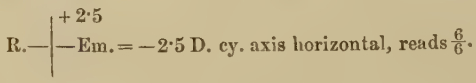
$$\frac{+6{\cdot}5\text{ D. sp.}}{+1\text{ D. cy. axis horizontal;}}$$

in this case, therefore, hypermetropia was present in one eye, compound hypermetropic astigmatism in the other.

Case 4. *Astigmatism.*—Young woman, aged 17, sees with either eye $\frac{6}{24} - 1$ D. $= \frac{6}{18}$. Retinoscopy with atropine—



Ordered guttæ atropiæ sulphatis, gr. iv to ʒj, for three days; then with retinoscopy the result is—



After recovering from atropine the result was confirmed, and the following correction ordered to be worn constantly:

R. $\frac{-1 \text{ D. sp.}}{-2{\cdot}5 \text{ D. cy. axis horizontal.}}$

L. −3 D. cy. axis 130°.

Case 5. *Mixed Astigmatism.*—Mary E—, aged 15, pupil-teacher, brought up from Cardiff about her eyes; suffers much from headache and pain in the eyeballs, especially the right, worse in the evenings. Has tried many opticians to get spectacles to suit her, but has always been unable to do so. R. V. $\frac{6}{36}$ slightly improved with − 1 D. L. V. $\frac{6}{36}$ also slightly improved with − 1 D. On placing the patient in the dark room, retinoscopy at once shows the case to be one of mixed astigmatism, with the chief meridians horizontal and

vertical; we proceed to correct each meridian, and the result is—

$$\text{R.}\left|\begin{array}{l}-5\text{ D.}\\ \text{—}+1\text{ D.}\end{array}\right. \qquad \text{L.}\left|\begin{array}{l}-5\text{ D.}\\ \text{—}+1{\cdot}5\text{ D.}\end{array}\right.$$

On trying this combination before the right eye, $\frac{6}{12}$ is read. We express the vision of right eye thus:

$$\text{R.}\tfrac{6}{36}+1\text{ D. sp.}\bigcirc-6\text{ D. cy. axis horizontal}=\tfrac{6}{12}.$$

With the left eye the combination gives, with the cylinder not quite horizontal, but slightly outwards and downwards, $\frac{6}{9}$.

$$\text{L.}\tfrac{6}{36}+1{\cdot}5\text{ D. sp.}\bigcirc-6\text{ D. cy. axis }170^\circ=\tfrac{6}{9}.$$

The patient remarked that she had never seen things so clearly before. The result was very satisfactory, and was arrived at in about ten minutes, thus saving an infinite amount of time and trouble, which would have been required to work out such a case by any of the older methods. Ordered guttæ atropiæ sulphatis, gr. iv to ℥j, three times a day for four days, when the result was—

$$\text{R.}\left|\begin{array}{l}-4\text{ D.}\\ \text{—}+2\text{ D.}\end{array}\right. \qquad \text{L.}\left|\begin{array}{l}-4\text{ D.}\\ \text{—}+2\text{ D.}\end{array}\right.$$

$$\text{R.V.}\tfrac{6}{6}+2\text{ D. sp.}\bigcirc-6\text{ D. cy. axis }175^\circ=\tfrac{6}{6}.$$
$$\text{L.V.}\tfrac{6}{6}+2\text{ D. sp.}\bigcirc-6\text{ D. cy. axis }170^\circ=\tfrac{6}{6}.$$

In this case the glasses were again tried after atropine was recovered from, and the following glasses ordered, which were of course to be worn constantly:

$$\text{R.}\frac{+1\text{ D. sp.}}{-6\text{ D. cy. axis }175^\circ.} \qquad \text{L.}\frac{+1{\cdot}5\text{ D. sp.}}{-5{\cdot}5\text{ D. cy. axis }170^\circ.}$$

Case 6. *Mixed Astigmatism.*—Mr. C—, aged 24, has noticed that for the past few years the eyes become very tired at night, especially when much writing or reading has been done; he thinks he sees distant objects less clearly than formerly.

R. V. $\frac{6}{24}$ not improved with convex or concave glasses; with pin-hole test $\frac{6}{12}$.

L. V. $\frac{6}{18}$ not improved with convex or concave glasses; with pin-hole test $\frac{6}{12}$.

After using atropine for four days, retinoscopy gave the following results:

R.— | +3 D. / —+·5 D. L.— | +2·5 D. / —+·5 D.

R.V. $\frac{+\cdot5 \text{ D. sp.}}{+2\cdot5 \text{ D. cy. axis } 160°} = \frac{6}{6}$. L.V. $\frac{+\cdot5 \text{ D.}}{+1\cdot5 \text{ D. axis cy. } 165} = \frac{6}{5}$.

We direct the patient to return after the effects of the atropine have passed off, which he does in ten days; we then try our correction, deducting + 1 D. sphere for the atropine.

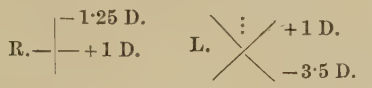
R.V. $\frac{-\cdot5 \text{ D. sp.}}{+2\cdot5 \text{ D. cy. axis } 160°} = \frac{6}{6}$. L.V. $\frac{-\cdot5 \text{ D.}}{+1\cdot5 \text{ D. cy. axis } 165°} = \frac{6}{5}$.

This correction was accordingly ordered to be worn constantly.

Case 7. *Astigmatism.*—Sarah K—, aged 21, complains that her eyes have of late been very painful, and she has also suffered much from headaches, which have sometimes ended with an attack of sickness.

R.V. $\frac{6}{18} - 1$ D. $= \frac{6}{12}$. L.V. $\frac{6}{24} - 2$ D. $= \frac{6}{18}$.

After atropine, retinoscopy gave—



R.V. $\frac{+1 \text{ D. sp.}}{-2{\cdot}25 \text{ D. cy. axis horiz.}} = \frac{6}{6}$. L.V. $\frac{+1 \text{ D. sp.}}{-4 \text{ D. cy. axis } 125°} = \frac{6}{9}$.

When the effects of the atropine had passed off, the correction which gave the best results was—

R.V. $-2{\cdot}25$ D. cy. axis horiz. $= \frac{6}{6}$. L.V. $\frac{+{\cdot}25 \text{ D. sp.}}{-4 \text{ D. cy. axis } 125°} = \frac{6}{9}$.

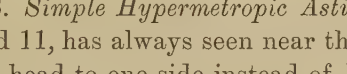
These spectacles were ordered to be worn constantly.

Case 8. *Simple Hypermetropic Astigmatism.*—Jane Q—, aged 11, has always seen near things badly; she turns her head to one side instead of looking directly at the object.

R. V. $\frac{6}{24}$ not improved with spheres, with pinhole $\frac{6}{18}$.

L. V. $\frac{6}{24}$ not improved with spheres, with pinhole $\frac{6}{18}$.

Retinoscopy after atropine gives—



R.V. $\frac{+1 \text{ D. sp.}}{+4 \text{ D. cy. axis vert.}} = \frac{6}{12}$. L.V. $\frac{+{\cdot}75 \text{ D. sp.}}{+3{\cdot}5 \text{ D. cy. axis vert.}} = \frac{6}{12}$.

After the atropine had passed off—

R.V. $+4$ D. cy. axis vert. $= \frac{6}{12}$. L.V. $+3{\cdot}5$ D. cy. axis vert. $= \frac{6}{12}$.

Spectacles of this strength were ordered for constant use.

Case 9. *Myopic Astigmatism.*—Jane P—, aged 23, has always seen rather badly, and has had a good deal of pain and discomfort in the eyes for the past six months, especially when using them by gas-light. About a week ago she noticed, on closing the left eye, that the vision of the right was almost gone, though she admitted never having tried them separately before; occasionally the right eye turns outwards.

$$\text{R.V.}\tfrac{1}{60} - 4\text{ D.} = \tfrac{6}{60}.$$
$$\text{L.V.}\tfrac{6}{24} - 1\text{ D.} = \tfrac{6}{18}.$$

Homatropine was applied once, and at the end of half an hour retinoscopy gave—

$$\text{R.}\left|\begin{array}{l} -5{\cdot}5\text{ D.} \\ --3\text{ D.} \end{array}\right. \qquad \text{L.}\left|\begin{array}{l} -1\text{ D.} \\ -\text{Em.} \end{array}\right.$$

With glasses—

$$\text{R.V.}\frac{-3\text{ D. sp.}}{-2{\cdot}5\text{ D. cy. axis }175^\circ} = \frac{6}{12}.$$
$$\text{L.V.} -1\text{ D. cy. axis }5^\circ = \frac{6}{6}.$$

This correction was ordered for constant use.

In most cases thus worked out the glasses may be ordered at once, without waiting for the effects of the atropine to pass off,—in fact, experience teaches that it is a good plan to continue the atropine until the spectacles have been made; remembering when ordering the correction that in hypermetropia and hypermetropic astigmatism the spherical glass will require slightly diminishing, usually about 1 D.; in myopia and myopic astigmatism the spherical glass has to be slightly increased.

CHAPTER VI

HYPERMETROPIA

Hypermetropia [Gr. ὑπέρ, beyond; μέτρον, measure, and ὤψ, eye] may be defined as a condition in which the antero-posterior axis of the eyeball is so short, or the refracting power so low, that parallel rays are brought to a focus behind the retina (the accommodation being at rest). In other words, the focal length of the refracting media is greater than the length of the eyeball.

FIG. 69

Parallel rays from ∞ brought to a focus behind the retina (dotted lines) from the retina emerge as diverging rays, as in

In the normal hypermetropic eye, therefore, parallel rays A and B come to a focus behind the eye at b, forming on the retina as a circle of diffusion instead

of a point. Rays coming from the retina of such an eye emerge having a divergent direction (D and E); these, if prolonged backwards, will meet at K, which is the punctum remotum, and this point being situated behind the eye is called *negative*.

The distance of the punctum remotum behind the eye will equal the focus of the convex lens which corrects the hypermetropia; thus, supposing the p. r. situated 20 cm. behind the retina ($\frac{100}{20} = 5$), 5 D. will be the convex glass which will render parallel rays so convergent that they will focus on the retina, or cause rays from the retina to be parallel after passing through it; to be mathematically correct, allowance

FIG. 67.

Parallel rays focussed on the retina by accommodation. The dotted line shows the lens more convex as a result of the contraction of the ciliary muscle.

must be made for the distance between the cornea and the convex lens; thus, for instance, if the lens be placed 20 mm. from the cornea, then the exact amount of hypermetropia which the + 5 D. glass will correct will be—

$$\frac{1000}{200 - 20} = \frac{1000}{180} = 5{\cdot}55.$$

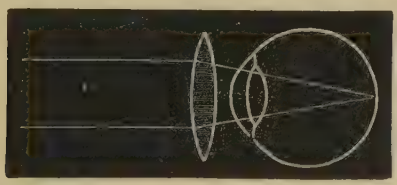
In low degrees of hypermetropia the difference is

so slight as to be unimportant; in the higher degrees the difference is considerable.

The hypermetropic eye at rest is only able to bring *convergent* rays to a focus on the retina. All rays in nature are divergent, some so slightly so, that when coming from a distant object they are assumed to be parallel. Rays can be made convergent by passing them through a convex lens placed in front of the eye; or the refraction of the dioptric system may be increased by the accommodation, so that parallel rays may then focus on the retina of a hypermetropic eye.

Therefore a hypermetrope with relaxed accommodation see all objects indistinctly. So that such a person, having to use some of his accommodation for distance, starts with a deficit for all other requirements, equal to the amount of hypermetropia.

Fig. 68.



Parallel rays rendered so convergent by passing through a convex lens that they focus on the retina.

Thus, supposing an individual hypermetropic to the extent of four dioptres, and possessing 6 D. of accommodation, he will, by the exercise of this power

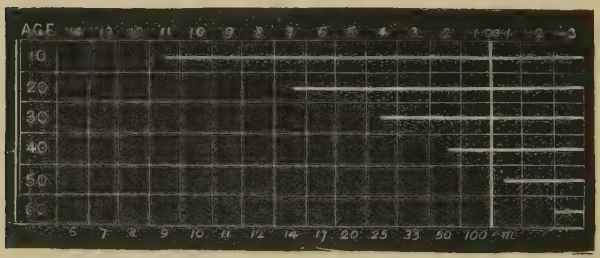
to the extent of 4 D., be able to bring parallel rays to a focus on the retina, and so see distant objects clearly; this leaves him 2 D. of accommodation for near objects, which will bring his near point to 50 cm., a distance at which he will be unable to read comfortably.

Besides, it must be remembered that only a part of the accommodation can be used for sustained vision, fatigue soon resulting when the whole of the accommodation has to be put in force.

The following diagram is intended to show the amount of accommodation possessed by a hypermetrope of 3 D.; each space represents a dioptre, and the thick white lines drawn through the spaces give

Fig. 69.

Dioptres.



the amplitude of accommodation for different ages as given on the left of the diagram. The figures above indicate the number of dioptres, and those below, the near point for each increasing dioptre of accommodation.

The amount of hypermetropia is calculated and expressed by that convex glass which makes parallel rays so convergent that they meet on the rods and cones of the retina, the accommodation being suspended.

The commonest amount of error is about 2 D. Small degrees may require some trouble to discover, and can only be found out possibly after the eye has been atropized.

Hypermetropia is divided into *latent* and *manifest*. The manifest, Donders subdivides into *absolute, relative,* and *facultative :*

Absolute, when by the strongest convergence of the visual lines accommodation for parallel rays is not attained—in other words, when distant vision is impaired ; this variety is seldom met with in young people.

Relative, when it is possible to accommodate for a near point, by converging to a point still nearer,—in fact, by squinting.

Facultative, when objects can be clearly seen with or without convex glasses.

In youth the hypermetropia may be facultative, becoming in middle age relative, and in old age absolute.

Causes of Hypermetropia :

1. The antero-posterior diameter of the eyeball is too short (axial hypermetropia). This is by far the most common cause, and is congenital.

2. A flattened condition of the cornea, the result of disease or occurring congenitally.
3. Absence of the lens (aphakia).
4. Detachment or protrusion of the retina, owing to a tumour or exudation behind it.
5. A diminution in the index of refraction of the aqueous, lens, or vitreous.

Hypermetropia, therefore, is usually due to shortening of the axis of the eyeball.

The following table shows the amount of shortening for each dioptre of hypermetropia, the axial line in emmetropia being estimated at 22·824 mm.

For ·5 of D.	of	H.	there is a diminution in the axial line of	·16 mm.
1·D.	„	„	„	·31 „

Hypermetropia is by far the most frequent condition of the refraction. It may be looked upon as a congenital defect; frequently also it is hereditary, several members of the same family suffering from it.

Hypermetropia is usually due to an arrest of deve-

lopment, which varies from the slightest degree to the extreme condition known as "microphthalmos."

The following are some of the chief points in which the hypermetropic differs from the emmetropic eye :— the eye looks small, being less than the normal in all its dimensions, especially the antero-posterior; the sclerotic is flat, and makes a strong curve backwards in the region of the equator, which can easily be seen on extreme convergence, or can be felt by the finger. The lens and iris are more forward, the anterior chamber is shallow, and the pupil small; the centre of rotation of the eye is relatively further back, while the angle *a*, which is formed between the visual and optic axis, is invariably greater, averaging about 7° (see p. 202). The result of the large angle *a* in hypermetropia is that the eyes often have an appearance of divergence, which has sometimes been mistaken for real divergence; whereas in myopia the small angle gives to the eyes an appearance of convergence.

The ciliary muscle, upon the action of which the accommodation depends, is much larger than in emmetropia, the anterior portion, which consists chiefly of circular fibres, being especially developed; no doubt hypertrophied by the constant state of contraction in which it is kept. This contraction is called into action by the instinctive desire for clear images which all eyes possess, the accommodation having to be used for distant as well as for near objects. Another result of the constant and excessive accommodation is that its linked function—the

convergence—is liable also to be used in excess; in this case an object at a certain distance being accommodated for, one eye will be directed to the object, while the other, taking up the excessive convergence, will be directed inwards, and so a *convergent strabismus* will be produced. To fully understand how this convergent strabismus becomes developed, I must refer the reader to the chapter on that subject (Chap. X).

When the hypermetropia is of high degree the optic nerve is smaller, and contains fewer fibres, so that the visual acuteness is frequently below the normal.

Sometimes the face also has a characteristic appearance, being flat-looking, with depressed nose, the orbits being shallow, and the eyes set far apart. Frequently, however, there is no distinctive physiognomy.

The hypermetropic eye is very liable to asymmetry, as will be shown when speaking of astigmatism.

Symptoms of Hypermetropia.—The patient usually sees well at a distance, but has difficulty in maintaining clear vision for near objects; and since the hypermetropia can be more or less corrected by accommodation, if the error be of a low degree (as 2 or 3 D.), no ill effects may for some time be noticed; at length, however, a point is reached when the accommodation is not equal to long-sustained efforts of reading and near work, then accommodative asthenopia is the result (p. 225). This is especially liable to show itself after an illness, or if the patient's health has deteriorated from over-work, anxiety, or

other causes. He then complains that after working or reading for some time, especially during the evenings, the type becomes indistinct, and the letters run together; after resting awhile the work can be resumed, to be again shortly laid aside from a repetition of the dimness: the eyes ache, feel weak, water, etc., frequently headache supervenes; there is a feeling of weight about the eyelids, and a difficulty in opening them in the morning. When the hypermetropia is of high degree, the patient may be said by his friends to be short-sighted, because when reading he holds the book close to his eyes; by doing this he increases the size of his visual angle, and thus gets larger retinal images; this is counterbalanced by increase in the circles of diffusion, but as the pupils also contract by approaching the book to his eyes, some of these are cut off; so that the advantage is in favour of holding the book close, especially as the patient is probably not accustomed to clear, well-defined images. In some cases the ciliary muscle contracts in excess of the hypermetropia, so that parallel rays focus in front of the retina, and the patient therefore presents many of the symptoms of myopia: we should always be on our guard against such cases. The manner in which the patient reads the distant type is often a guide to us in hypermetropia; he takes a considerable time to make out each line, and yet, if not hurried, eventually reads the whole correctly. On looking at the eyes one notices that they are red and weak, the lids look irritable, and on eversion the conjunctiva is hyperæmic, espe-

cially that of the lower lids, while the papillæ are frequently enlarged; the edges of the lids sometimes become inflamed and thickened. All these symptoms are probably the commencement of troubles which, if allowed to go on, may develop into conjunctivitis, derangements of the lacrymal apparatus, etc.,—this much we can see; how much more injurious must be the changes which are liable to take place in the interior of the eyeball from prolonged hyperæmia! It cannot be too forcibly insisted on, that in all ophthalmic cases, except those of an acute character, the refraction should be taken and recorded as a matter of routine, since complaints which prove very intractable are often easily and quickly cured when the proper glasses have been prescribed.

As the patient advances in age he will become prematurely presbyopic, so that at thirty-five he may suffer from the same discomforts as an emmetrope of fifty.

To test the hypermetropia and measure the amount, we take the patient's visual acuteness, each eye separately, and having found that they are alike in their refraction, we try the two together; stronger glasses being often borne when both eyes are used, than when one is excluded from vision.

The *strongest* convex glass with which he is able to read $\frac{6}{6}$, or with which he gets the greatest acuteness of vision, is the measure of the *manifest* hypermetropia (Hm.). This is not, however, the total hypermetropia, for if the accommodation be paralysed by applying a solution of atropiæ sulph., gr. iv to ℥j,

three times a day for four days (when we may feel sure that not the least vestige of accommodation remains), a much stronger glass can be tolerated, and will be required to enable the patient to read $\frac{6}{6}$. This strong glass represents the total hypermetropia, the additional amount to that found as Hm. being called *latent* (Hl.).

The following plan is an excellent one for measuring the manifest hypermetropia. Place in spectacle-frames before the eyes such convex lenses as over-correct the Hm. (+ 4 D. will usually do this); then hold in front of these, weak concave glasses, until we find the *weakest*, which thus held in front of + 4 D. enables $\frac{6}{6}$ to be read; the difference between the glasses is then the measure of the Hm. By this plan the ciliary muscle is encouraged to relax, and we get out a larger amount of manifest hypermetropia than is obtained by the ordinary method. Thus, supposing − 2 D. the weakest glass which, held in front of the convex 4 D., enables the patient to read $\frac{6}{6}$, + 2 D. is the measure of the Hm. (+ 4 D.) + (− 2 D. = + 2 D.).

As age advances the accommodation diminishes, and the latent hypermetropia becomes gradually manifest. Thus a person may have 6 D. of hypermetropia latent at ten years of age, 3 of which may have become manifest at thirty-five, and the whole of it at about sixty-five or seventy, when the total hypermetropia is represented by the manifest.

With the advance of age certain changes take place in the structure of the crystalline lens, by

which its refraction becomes diminished. This change takes place in all eyes, and at a regular rate; thus at fifty-five the refraction has diminished ·25 D., at sixty-five ·75 D., at sixty-eight 1 D., and at eighty as much as 2·5 D. Hypermetropia when thus occurring in eyes previously emmetropic is styled *acquired hypermetropia*, in contradistinction to the congenital form, which is called *original hypermetropia*.

The normal refraction of the eye in early childhood is hypermetropic; some remain so, a considerable number become emmetropic as they get older, and a certain percentage of these pass on to myopia.

In the diagnosis and estimation of hypermetropia several methods are useful. We first estimate the *acuteness of vision*, remembering that being able to read $\frac{6}{6}$ does not exclude hypermetropia, and that we must in all cases try convex glasses; and if the same letters can be seen with as without them, then the patient certainly has hypermetropia, and the *strongest* convex glass with which he sees them is the measure of his Hm.

We next proceed to **retinoscopy**; with this method we get a reverse shadow: the quicker the movement and the brighter its edge, the lower is the degree of hypermetropia (see p. 95).

With the ophthalmoscope by the **indirect method** of examination, the image of the disc is larger than the emmetropia, and diminishes on withdrawing the objective from the eye (p. 69).

With the **mirror alone at a distance,** an erect image

of the disc is seen, which moves in the same direction as the observer's head (p. 73).

By the **direct method** the accommodation of the observer and observed being relaxed, a convex glass is necessary behind the ophthalmoscope, to enable the observer to bring the diverging rays from the observed eye to a focus on his retina; the strongest *convex* glass with which it is possible to see the details of the fundus clearly, is the measure of the total hypermetropia (Fig. 47).

The treatment of hypermetropia consists, obviously in prescribing such convex glasses as will give to rays passing through them an amount of convergence, so that they will meet on the retina without undue accommodation. It might be thought that, having obtained the measure of the *total* hypermetropia, nothing remained but to give such positive glasses as exactly neutralise the defect, and that we should then have placed the eye in the condition of an emmetropic one. Such at first was thought to be the case, though it is by no means so, because persons who have been accustomed to use their accommodation so constantly, both for near and distant objects, as in the case with hypermetropes, have very large ciliary muscles which they cannot suddenly completely relax; possibly also the elasticity of the lens capsule is somewhat impaired.

In children and patients under twenty years of age it is much better to atropize them at the first, and so measure once and for all the amount of total hypermetropia; otherwise it will frequently be found that

the spectacles have to be constantly changed, the asthenopia is unrelieved, and probably the patient has to be atropized after all, or becomes dissatisfied and goes off to some one else. Another reason in favour of atropine is, that with it we cannot possibly mistake cases of spasm of the ciliary muscle in hypermetropia for myopia, which might otherwise happen, since the spasm causes the lens to become so convex that parallel rays are even made to focus in front of the retina, thus simulating myopia.

It must always be borne in mind that it is dangerous to atropize patients above the age of thirty-five, many well-marked cases of "glaucoma" having been traced to the use of this drug; moreover as age advances the latent hypermetropia gradually becomes manifest, so that the necessity for paralysing the accommodation becomes less.

There exists some difference of opinion among ophthalmic surgeons as to the amount of the total hypermetropia we ought to correct; some give such glasses as neutralise the *manifest* hypermetropia only, while others, after estimating the total, deduct perhaps 1 D. from this. It will be found that patients vary much as to the amount of correction which is most comfortable for them.

A good practical rule is to prescribe such glasses for reading as correct the *manifest* and one third of the *latent* hypermetropia.

For example, a child having 6 D. of hypermetropia of which 2 only are manifest, will require + 3 D. for reading. At the age of twenty, about

4 D. will have become manifest, and the patient will then want + 4·5 D.; at forty, 5 D. will be manifest, and he may then be able to bear full correction.

Hence it will be seen that, as age advances, the spectacles will have occasionally to be changed for stronger ones, as the latent hypermetropia gradually becomes manifest.

The question arises, should spectacles be worn constantly or only for near work? So long as distant objects ($\frac{6}{6}$) can be seen comfortably without them, their use is unnecessary except for reading and near work; this is generally the case in young persons where the hypermetropia does not exceed 3 or 4 D. When a convex glass improves distant vision, then such can be constantly worn; somewhat stronger ones may be required for reading, etc.; this is usually the case with old people.

The disadvantage of using spectacles constantly is, that after wearing them for some time the patient finds he is unable to see without them, which is a serious inconvenience; so that the plan is not to give spectacles for constant use until the hypermetropia has become relative or absolute.

In cases of concomitant squint, spectacles which correct the hypermetropia are to be worn constantly, and here our object must be to give as near the full correction as is consistent with the patient's comfort; this we can only find out by experiment in each case. The best plan is to measure under atropine the total hypermetropia, deduct 1 D., and give this correction for constant use: the reason for making this deduc-

tion is that the ciliary muscle is never so completely relaxed as when under atropine.

Convergent strabismus and asthenopia, two of the most frequent results of hypermetropia, will be treated of in Chapters X and XI.

See Cases 1 and 2, p. 110; also 10, 12, and 17, p. 242.

Aphakia

Aphakia (' A, priv ; φακὸς, lens) is the name given to that condition of the eye in which the lens is absent. There are several causes, by far the most frequent being one of the various cataract operations. Besides this aphakia may be caused by dislocation of the lens from injury, or dislocation may occur spontaneously, and this is probably the cause of those congenital cases where no lens can be seen.

Aphakia necessarily converts the eye into a very hypermetropic one. The length of the eyeball which would be required (the curvature of the cornea being normal and the lens absent) to bring parallel rays to a focus on the retina is 30 mm., whereas normally the antero-posterior diameter of the eyeballs is only about 22·8 mm.

To test aphakia: when a bright flame is held in front of and a little to one side of a normal eye, three images of the flame are formed, one erect on the cornea, another erect on the anterior surface of the lens, and a third inverted, and formed on the posterior surface of the lens. On moving the flame up and down, the erect images move with it, and the

inverted one in the opposite direction. In aphakia two of these images are absent, viz., those formed on the two surfaces of the lens.

Treatment.—Strong convex glasses will be required to take the place of the absent lens, the previous refraction of the eye of course influencing their strength. If hypermetropic, stronger glasses will be required; if myopic, weaker.

The convex glass usually required by an eye previously emmetropic, to bring parallel rays to a focus on the retina is from 10 to 13 D.

As every trace of accommodation is lost with the lens, stronger glasses will be required for reading or near work, and to find out the necessary glass for a certain distance, we have only to add to the distance glass one whose focal length equals the distance at which we wish our patient to see. Thus, if he require + 10 D. for distance, and wish to see to read at 25 cm., we add + 4 D. to his other glass, and the resulting + 14 D. will adapt the eye to 25 cm.

The patient may be taught a sort of artificial accommodation by moving the spectacles along his nose, nearer or farther from the eyes, his working point being thereby moved away or brought nearer to him.

In correcting aphakia it will often be found that the vision is below the normal. Frequently also there is some astigmatism, especially in cases after cataract extraction.

See Case 23, p. 256.

CHAPTER VII

Myopia (m.)

Myopia (Μύω, I close: ὤψ, the eye), or short-sight, is the opposite condition to hypermetropia.

We saw that the hypermetropic eyeball was too short, so that parallel rays focussed behind the retina; it is therefore not adapted to any real distance, because in order to see any object clearly, it is necessary that the defect should be corrected either by the accommodation or by means of a convex glass. Now in myopia, although the eyeball is too long to allow of distant objects being seen clearly, it is perfectly adapted for near vision, so that a low degree of myopia may not be a very serious disadvantage.

We spoke of hypermetropia as congenital, due to an arrest of development; myopia is an acquired defect, and may be looked upon as an effort of nature to adapt the eye to near objects, as a result of civilisation and its incessant demands on near vision.

Myopia is peculiar to the human race, and is met with much more frequently in civilised than in uncivilised races.

Low degrees, such as 1 D., may have no very serious

drawbacks, because although the full visual acuteness can only be obtained by the help of concave glasses, many people go half through life, playing cricket, tennis, shooting, etc., without finding out the defect; their near vision is really better than that of the emmetrope, for they obtain larger retinal images, and they have to accommodate less; against these advantages it may be stated that many myopes suffer from asthenopia, the result of disturbance of the harmony between the two functions, accommodation and convergence, though this disturbance will, of course, be more marked in the higher degrees of ametropia.

Medium degrees of myopia, from 2 to 6 D., are exceedingly common; the visual defects are more pronounced, and it becomes necessary to use glasses for many things: often they have to be worn constantly. Such patients are liable to suffer from asthenopia, or from divergent strabismus and its accompanying evil —loss of binocular vision.

The higher degrees of myopia which increase steadily and constantly from an early stage, reaching often a very high degree, and carrying in its wake destruction and damage to important ocular tissues, must be looked upon as a serious disease; it is designated by the name *progressive* myopia.

We must now refer to the optical condition of the myopic eye.

Parallel rays, falling on a myopic eye, focus in front of the retina, cross and form a circle of diffusion (Fig. 70), in place of a clear image.

Only divergent rays focus on the retina, and hence

it is necessary that the object looked at be brought so near, that rays coming from it are sufficiently divergent (Fig. 71), or they must be rendered so by passing them through a concave lens (Fig. 72), before they fall upon the cornea.

Fig. 70

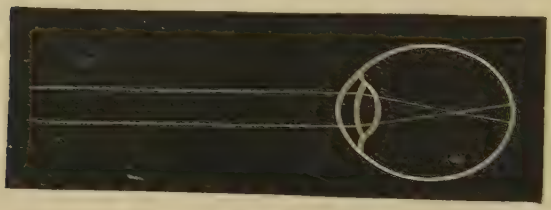

Fig. 71.

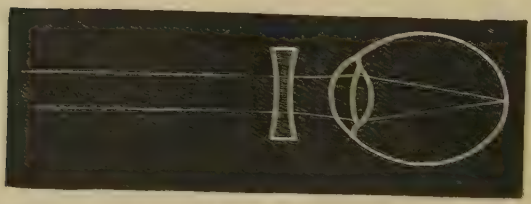
Fig. 72.



We may say, then, that in myopia the retina is at the conjugate focus of an object, situated at a finite distance. The accommodation being at rest, an

object situated at this point will be distinctly seen; further off it will be indistinct, nearer it can still be seen clearly by putting in force the accommodation.

The greatest distance at which objects can be seen clearly is called the far point (punctum remotum), and is always at a definite distance. The higher the myopia the nearer to the eye is its punctum remotum (p. r.).

The nearest point of distinct vision is the punctum proximum (p. p.), and is determined by the amount of the accommodation. To find out the punctum proximum, we place in the patient's hand the near type, and note the shortest distance for each eye separately at which the smallest type can be read, or we measure it by the wire optometer in the manner before described. The amplitude of accommodation is often equal to that in emmetropia, but in the higher degrees of myopia it becomes considerably diminished.

The greatest distance at which an object can be clearly seen is the exact measure of the myopia; for instance, if the far point be at one metre, a concave glass of that strength (− 1 D.) would render parallel rays as divergent as if they came from a distance of one metre, and with a glass of this focus the person would be able to see distant objects clearly.

Myopia was for a long time thought to be due to an increase in the convexity of the cornea, but as a matter of fact the cornea is usually less convex, and, as a rule, the greater the myopia the less the convexity.

Causes of Myopia:

1. Too great length of the antero-posterior diameter of the eyeball (axial myopia). This is the common cause of myopia.
2. Increase of the index of refraction of the lens. This may occasionally occur in the development of cataract.
3. Conical cornea: this disease simulates myopia at its commencement.

It may therefore be stated that myopia almost invariably depends upon a lengthening of the visual axis accompanied in many cases by the formation of a *posterior staphyloma* which further increases the antero-posterior diameter of the eyeball. This bulging, when it occurs, takes place at the outer side of the optic nerve towards the macula, and consists of an extension backwards with thinning of the sclerotic and choroid, and more or less atrophy of the latter.

So constant is this lengthening of the visual axis, that from the number of dioptres of myopia can be calculated the increase in the length of the eyeball.

The following table gives the calculation up to 10 D.

Degree of myopia.		Distance of the p. r. in millimetres.		Increase in length of the myopic eye in millimetres.
·5 D.	...	2000	...	·16
1·	...	1000	...	·32
1·5	...	666·6	...	·49
2·	...	500	...	·66
2·5	...	400	...	·83
3·	...	333·3	...	1·

Degree of myopia.		Distance of the p.r. in millimetres.		Increase in length of the myopic eye in millimetres
3·5	...	285·7	...	1·19
4·	...	250	...	1·37
4·5	...	222·2	...	1·55
5·	...	200	...	1·74
6·	...	166·6	...	2·13
7·	...	142·8	...	2·52
8·	...	125	...	2·93
9·	...	111·1	...	3·35
10·	...	100	...	3·80

Fig. 73 shows a section of a myopic eye, in which the outside measurements were—antero-posterior diameter, 30½ mm.; vertical diameter, 25 mm.; transverse diameter, 25 mm.

Fig. 73.

It will be remembered that the emmetropic eye measures in the antero-posterior diameter 22·824 mm.

In Fig. 74 the amount of accommodation is indicated in a myope of 2 D. by the number of spaces through which the thick lines pass; thus at the age of thirty the accommodation is equal to 7 D., and the near point will be 11 cm.; the distance of the punctum proximum is given for each dioptre at the bottom of the diagram.

As the punctum remotum in myopia is situated at a finite distance, therefore, for the same amplitude of accommodation, the punctum proximum is nearer the eye in myopia than in emmetropia. The near point

FIG. 74.

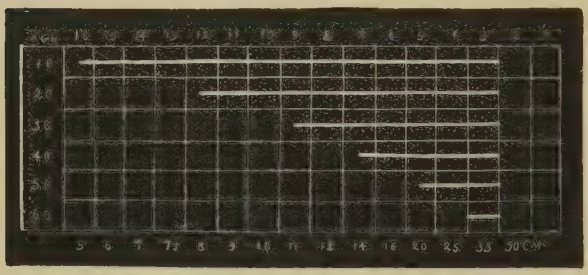


Diagram showing the amount of accommodation at different ages in a case of myopia of 2 D.

gradually recedes with advancing age at the same rate, whatever the refractive condition of the eye; it is clear, then, that the near point in myopia will be longer in reaching that point (22 cm.) at which presbyopia is arbitrarily stated to commence than in emmetropia, so that in prescribing glasses for presbyopia, the amount of myopia has to be deducted from the glass which the emmetrope would require at any given age.

If the myopia amount to 4·5 D., then the patient can never become presbyopic, because his punctum remotum is only 22 cm. away, so that he will always be able to see at that distance. Most people imagine that those who do not require glasses with advancing

age have very strong eyes; how frequently does one hear the remark, when inquiring of a patient's family history, "Oh, my father had excellent sight, he was able to read at sixty without glasses." This is proof positive that he had myopia, though probably you will be unable to convince the patient of this fact.

In hypermetropia it was shown that the power of accommodation had to be used in excess of the convergence. In myopia we have the opposite defect, the patient having to converge in excess of his accommodation; thus, if he be myopic 4 D., his far point will be at 25 cm.; when looking at an object at this distance, it is necessary for him to converge to this particular point, his angle of convergence being 4, while his accommodation remains passive.

Determining Causes.—The chief factors in the production of myopia are: the constant use of the eyes for near work, especially at an early age, when these organs are developing; disturbances of nutrition in the tissues of the eye, together in some cases with a peculiar conformation of the skull.

In a large majority of cases myopia is acquired, but in a small proportion of cases it may be congenital; this latter form frequently attains a high degree in early life, may occur in one or both eyes, and bears no relation to the occupation of the patient. Though seldom congenital it not infrequently happens that one or other of the parents has suffered from myopia.

There is little doubt that in many cases there is an hereditary tendency to it, which, transmitted through

several generations, under favourable conditions for its development, becomes very decided.

As in the greater number of cases of myopia the factor which tends to produce it is the prolonged use of the eyes on near objects, especially while young, we may set down myopia as one of the results of civilisation and education, and in these days of high pressure and competitive examinations it is constantly on the increase. The result of the very numerous statistics that have been collected, especially by German ophthalmologists (myopia in Germany is exceedingly common), points to the production of myopia in direct proportion to the amount of education. The amount of myopia was found to be much greater in town than in country schools, no doubt because the general health was better amongst those living in the country. Erismann has come to the pleasant conclusion that, if myopia increase in the same ratio as it had done during the last fifty years, in a few generations the whole population will have become "myopic."

The normal refraction of the eye in childhood is hypermetropic; some few remain so, a great number becoming emmetropic as they get older, and a larger percentage of these pass on to myopia.

In proof of this hereditary tendency to myopia, Dr. Cohn has summarised the statistics of various German writers on this subject. Thus in public schools, myopia was found to exist without predisposition in 8 per cent., with predisposition in 19 per cent. In the higher schools the result was—without

predisposition 17 per cent., with predisposition 96 per cent.

Residence in towns is also conducive to short-sight by causing people to gaze constantly at near objects.

The cause why myopia when once established is very liable to increase, is that the extreme convergence, which is necessary to enable the patient to see at the limited distance to which he is confined, causes the weakest part of the globe (that part, in fact, which is least supported) to bulge, forming a posterior staphyloma. In support of this method of the production of myopia may be stated the well-known fact, that people, such as watchmakers and jewellers, who habitually use a strong convex lens before one eye, and work at the focal distance of that lens, are not especially liable to myopia, proving that close work without convergence does not tend to produce it. As the eyeball becomes elongated, its movements become more difficult, and the pressure produced by the muscles during prolonged convergence tends still further to increase the myopia.

The stooping position which so many myopes take up, causes an accumulation of blood in the eyeball which tends to raise the tension as well as materially to interfere with its nutrition. Hence results a state of congestion, softening, and extension, leading to a further increase of the myopia. The more advanced these changes, the more difficult is it for the myopia to become stationary.

In addition to these two causes, extreme con-

vergence and the stooping position, it is possible that, as a result of the constant convergence, the optic nerves may be somewhat pulled upon, and thus further assist in producing myopia.

Cases of nebulæ, cataract, and other causes of imperfect sight in children may give rise to myopia by causing them to hold objects they wish to see close to the eyes.

Symptoms.—The patient sees distant objects badly and near objects well. The eyes look prominent; the pupils are usually large in young people; as age advances they contract, thus diminishing the circles of diffusion, and so slightly improving vision. Eserine acts in the same manner, so does the nipping together of the eyelids, which is so characteristic of patients suffering from myopia, and to which the disease owes it name. The acuteness of vision is frequently below the normal, though objects within the patient's far point appear larger than they do to the emmetrope, the distance between the nodal point and the retina being greater in myopia (Fig. 75). This, however, may be partly counterbalanced by the stretching of the retina, so that, although the image may be somewhat larger, it may not cover a greater number of cones than would be the case in an emmetropic eye.

If the myopia be progressive, frequent limitations in the field of vision occur, in the form of scotomata due to patches of retinal atrophy.

Besides seeing distant objects badly, the patient complains of pain, fatigue, and intolerance of light,

with a state of irritation, especially after using the eyes by artificial light. There may be hyperæmia

FIG. 75.

A. The retina in an emmetropic eye. B. The retina in a myopic eye. C. The visual angle. N. The nodal point. The distance from N B is greater than N A, and the image of O P is greater at B than at A.

of the eyes and lids, spasm of the accommodation (which increases the apparent amount of myopia), pain in the eyeballs on pressure, photopsia, an appearance of convergence due to the small size of the angle *α* (p. 202), together with "muscæ volitantes." These are often a source of great anxiety; the patient may, however, be assured that, although they cannot be removed, there is no cause for uneasiness; these muscæ are probably the remains of vitreous cells, which, being situated a considerable distance in front of the retina, throw shadows on it, and are projected outwards as much larger images than would be the case in an emmetropic eye; they appear to the patient as black spots.

The ciliary muscle is smaller than in emmetropia, the circular fibres (which are so hypertrophied in hypermetropia) being almost absent.

The internal recti muscles often act badly, so that convergence becomes painful and difficult, often going on to divergent strabismus.

In myopia the convergence has to be used in excess of the accommodation; some patients as they become myopic learn to use these two functions in unequal degrees, while others are unable thus to dissociate them; so that on looking at an object situated at the myope's far point, no accommodation and no convergence take place, it becomes necessary then that the two eyes shall make a conjugate movement in one direction, so that one eye may receive the image of the object on its mucula, while the other eye as a result of the conjugate movement has deviated outwards,—in other words, divergent strabismus has occurred.

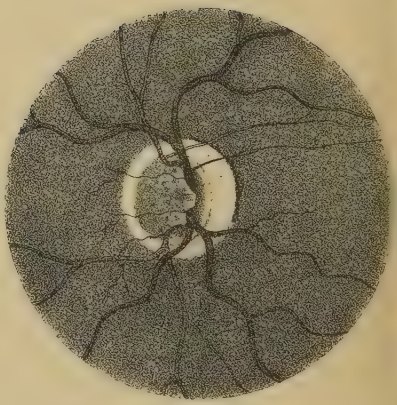
When the myopia is of high degree, the patient often uses one eye only for reading, then of course he does not require to converge.

The refraction diminishes slightly with advancing age (see p. 128); the pupils also become smaller, thus cutting off some of the patient's circles of diffusion; so that frequently a marked improvement takes place in the vision of myopes as they get older.

Ophthalmoscopic Appearances.—With the ophthalmoscope, a crescentic-shaped patch of atrophy is frequently seen on the outer side of the optic disc, embracing it by its concave edge; this is called the "myopic crescent."

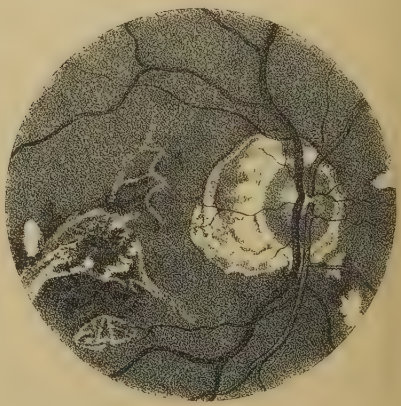
In an early stage the crescent looks somewhat white, the large choroidal vessels often appear more

1.



2.

3.



4.

Bale & Danielsson Ltd. lith.

distinct than on the adjoining parts, while gradually the blood-vessels disappear, leaving the white sclerotic, which shows up plainly against the red of the fundus. Some remains of pigment about the convex border of the crescent are often seen, and frequently there is some thinning of the choroid beyond. The retina seems to participate in this atrophy much less than might have been expected.

Although the atrophy usually assumes the crescentic form, as shown in Plate 1, which was drawn from the fundus of a young man, aged twenty, with a myopia of 4 D., yet it may vary much, sometimes forming a complete ring round the optic disc (2), or it may extend outwards (3), the broadest part being always between the disc and the macula. Sometimes there is excavation of the atrophic part.

The optic nerve is occasionally displaced somewhat inwards, and the disc, instead of being directed forwards, looks forwards and outwards, making it appear oblong in shape from its being seen obliquely (3); The retinal vessels that pass over the atrophied part are often straight in their course, and show up very clearly against the white sclerotic.

The formation of the crescent is much influenced by the amount of myopia. In slight degrees in young people it is often absent, but in cases of 6 D. or more, at the age of twenty, we invariably find a well-marked crescent.

In very high degrees of myopia the epithelial layer of the retina atrophies, secondary changes may take place in the yellow spot, as shown in Plate 4:

when such changes take place they cause great impairment of vision, due either to extension of the atrophy outwards, or to disease commencing there independently. If the disease be progressive, the vitreous becomes disorganised, with floating opacities; the nutrition of the lens may suffer, opacities forming in it, especially at the posterior pole; choroidal hæmorrhages may occur, and detachment of the retina sometimes takes place.

Further, it may be said that myopes, owing to their defective vision, are especially liable to accidents.

The **diagnosis and estimation** of myopia is easy. At the distant type the patient requires a concave glass to enable him to read $\frac{6}{6}$. The *weakest* lens with which he is able to read it is the measure of his myopia; always remember the patient is apt to choose too strong a glass if left to himself; to prevent this and enable us to make an exact record of the condition of the refraction, by which we may judge if the myopia is stationary or progressive, it is much the best plan in young people to atropise them in the manner previously described. Great differences will be found in myopes when testing them at the distant type: in some, each increase in the strength of the glass causes a corresponding increase of vision; while in others, with the same amount of myopia, but little improvement takes place until nearly the full correction is reached, when it suddenly becomes almost normal: hence it is not sufficient after trying two or three concave glasses without any visual improvement, to at once assume the absence of myopia. On placing

the near type in his hand, he will be found to be able to read the smallest print, though at a *shorter* distance than that for which it is marked. The extreme distance at which he is thus able to read it is his far point, the measure of which is also a measure of his myopia; this is a most useful guide to us: for instance, he reads No. 1 at 20 cm. but no farther; $\frac{100}{20} = 5$ D., therefore 5 D. is the measure of the myopia, and such a glass will render parallel rays so divergent that they will seem to come from 20 cm. Had he been able to read it at 10 cm. only, then $(\frac{100}{10} = 10$ D.$) - 10$ D. would be the measure of the myopia.

With **retinoscopy** the shadows move in the same direction as the concave mirror so long as the observer is beyond the patient's far point (p. 90).

With the ophthalmoscope, by the **indirect** examination, the disc looks smaller than in emmetropia, and becomes larger on withdrawing the objective farther from the eye (p. 70).

With the mirror alone at a distance, an inverted magnified image of the disc can be clearly seen, provided always that the observer be not nearer the aërial image than his own near point (Fig. 45). The lower the myopia the greater the image, because the longer is the distance between the image and tho myopic eye. On moving the head from side to side the image will always move in the opposite direction, showing that it is an inverted one.

By the **direct method** of examination the fundus cannot be clearly seen until a concave glass is placed in

front of the observing eye. The *weakest* concave glass with which the details of the macula and disc can be clearly seen (the observer's eye being emmetropic and the accommodation relaxed) is a measure of the myopia (Fig. 48). This test may be relied upon for the lower, but not for the higher degrees of myopia.

The **treatment** of myopia.—The chief indications are—

1st. To prevent the increase of the myopia.

2nd. To enable the patient to see well.

3rd. To prevent the various troubles from which myopes are so liable to suffer, as asthenopia, divergent strabismus, etc.

To carry out the first of these indications, strong convergence and the stooping position, which play so important a part in the production of myopia, must be avoided, the patient being directed never to read in a train or carriage, where every movement requires a change in the accommodation, nor to look at near objects for too long together: the natural tendency for a myope who is excluded in great measure from seeing distant objects, is to devote himself to near ones. In reading, writing, or working, he must keep 35 cm. away from the book or paper, use books printed in good bold type, and not write too small, while the desk and seat should be conveniently arranged so as to avoid stooping. He should do as little as possible by artificial light; when necessary, it is best to use a reading lamp, so placed that it throws the light down upon the work, leaving the remainder of the room in comparative darkness, so

that when the eyes become tired they may be rested by turning them from the light. The stooping position must be strictly avoided, as it causes an increased flow of blood to the interior of the eyeball, and at the same time, by compressing the veins in the neck, obstructs the returning blood, and so produces hyperæmia with symptoms of irritation, and possibly some slight increase of tension. When reading or writing he should sit with his back to the window, so that the light may fall on the book or paper over his left shoulder, the shadow of his pen being thus thrown to the right, enabling him to see plainly the letters he is forming.

Attention must be paid to the general health; iron internally often being especially useful, combined with regular outdoor exercise and good nutritious food.

When symptoms of irritation show themselves, with a rapid increase in the myopia, complete rest must be given to the eyes, and in no way can this be so conveniently carried out as by dropping into the eyes a solution of atropine (gr. j to ʒj) three times a days, for some two or three weeks; counter-irritation may be applied to the temples and behind the ears in the shape of small blisters, or by a solution of iodine: no spectacles must be allowed. Sometimes, where there are symptoms of congestion present, the artificial leech applied to the temple once a week for a few weeks does much good. As the irritation gradually subsides, the patient may be allowed to do a little reading daily in a good light, the eyes all

the time being kept under atropine; he may require glasses to enable him to do this. Thus if he have myopia of 3 D. he will not require them, his far point being at 33 cm.; if he has − 1·5 D. he will require + 1·5 D. to enable him to read at about 33 cm. (+ 3 D.) + (− 1·5 D.) = + 1·5 D.; if the myopia is 6 D. he will require − 3 D. to put back his far point from 16 to 33 cm. (+ 3 D.) + (− 6 D.) = − 3 D.

So long as the myopia is progressive it must always be a source of anxiety to us.

To enable the patient to see well both near and distant objects, as well as to prevent extreme convergence, we must correct the myopia. In young people with good accommodation and with a low degree of myopia the full correction may be well borne, the patient wearing such glasses constantly; and it has been observed that in those who from their youth have worn their full correction constantly, for both near and distant objects, the myopia has usually remained stationary.

There are two exceptions to this general rule of the full correction of myopes:

1st. Where the myopia is of high degree, and the acuteness of vision is reduced, then the concave glasses so much diminish the size of the retinal images, that the individual is induced to make these images larger by bringing the object closer.

2nd. When the myopia is of high degree, and the patient has, from long custom, become used to exercise the function of convergence in excess of his accommodation, the full correction, which gives him

perhaps excellent distant vision, causes him pain when used for near objects. Here we must give two pairs of spectacles, one for distant vision, and the other for near objects; the latter may be gradually increased in strength as the patient becomes accustomed to them, so that after a time, possibly a year or so, the full correction may be comfortable for constant use.

In those cases where the myopia is of high degree, and the patient is unable to bear the full correction for reading, we find out the necessary glass by subtracting from the lens which gives the best acuteness of vision, that glass whose focus represents the distance at which the patient wishes to read or work. Thus, for example, — 9 D. gives the best distant vision; the patient wishes for glasses with which to read at 33 cm. (— 9 D.) + (+ 3 D.) = — 6 D.); — 6 D. will be the glass required, and will enable the patient to read at 33 cm. without using his accommodation.

Glasses may also be required for music. When the myopia is of low degree, and we are certain that the disease is stationary, folders may be allowed for distance, no glass being used for near work.

Single glasses are occasionally allowed in low degrees of myopia for looking at distant objects; they have the disadvantage that they encourage the patient to give up binocular vision, and may so assist in the development of a divergent squint.

When muscular asthenopia is present, prisms with their bases inwards (which diminish the necessity for

convergence), with or without concave glasses, are of great value.

When photophobia is a prominent symptom tinted spectacles may be comfortable (p. 235).

It is important to impress on the patient that the glasses for reading are not given to enable him to see better, but to *increase the distance* at which near work can be done.

When the myopia has been estimated under atropine, it is often necessary to add on to the glass so found − ·5 D., as the full correction under the mydriatic is usually this much weaker than the correction found without it, the reason being that the ciliary muscle is never so completely relaxed as it is by atropine.

I am of course aware that the above optical treatment of myopia is at variance with the teaching of French authorities.

Landolt considers that the action of the ciliary muscle may have a tendency to increase the myopia, and therefore states that myopes should never wear glasses which require the patient to use his accommodation: so that in low degrees of myopia glasses are only allowed for distant objects; in medium degrees, glasses which under-correct the myopia are given for near objects, so as to enable the wearer to see at a given distance without accommodation.

My own opinion is, that every case requires treating on its own merits; very many myopes wear their full correction constantly with comfort, and if not with benefit to the eyes most certainly without injury;

while other myopes will occasionally be found who suffer from asthenopia when using their full correction for near vision. In extreme degrees of myopia, and in those where the disease is increasing rapidly, rest for the eyes, and not spectacles, is the essential treatment.

In cases of high myopia (over 15 D.) the lens may be removed by a needle operation followed by curetting, and thus the eye may be brought nearly to the point of emmetropia, the patient getting good distant vision without glasses. Many of these cases have given most gratifying results. Usually only one eye is operated upon.

See Cases 11 and 19, pp. 245 and 253.

CHAPTER VIII

ASTIGMATISM AND ANISOMETROPIA

Astigmatism ('A, priv ; *στίγμα*, a point).

Hitherto we have seen that the cornea usually takes but little part in the defects we have been considering. It has been shown that hypermetropia is almost invariably due to the eyeball being too short, and myopia to its being too long. We now come to a defect in which the curvature of the cornea plays a very important part, with or without some decrease or increase (from the emmetropic standard) in the antero-posterior diameter of the eyeball; I refer, of course, to astigmatism, which is the commonest of all the refractive errors, few cases of hypermetropia being entirely free from it, and still fewer cases of myopia. Astigmatism may be defined as that state in which the refraction of the several meridians of the same eye is different: for instance, the vertical meridian may be emmetropic, the horizontal hypermetropic.

Astigmatism is usually congenital, but may be acquired; frequently there is some hereditary tendency.

Astigmatism was first discovered by Thomas Young in 1793, who was himself astigmatic.

Astigmatism may be divided into two chief varieties:

1. Irregular.
2. Regular.

Irregular astigmatism consists in a difference of refraction in the different parts of the same meridian, and may be further subdivided into *normal* and *abnormal*. (*a*) Normal irregular astigmatism is due in great measure to irregularities in the refracting power of the different sectors of the lens; it causes a luminous point to appear stellate, as in the case of a star, which is, in reality, round. (*b*) The abnormal variety may arise from the condition of the lens or of the cornea: when the lens is at fault, it may be a congenital defect, or it may be acquired from changes taking place in the lens itself; or it may result from partial displacement. The changes in the cornea which may produce it are, conical cornea, nebulæ, and ulcers. Little can be done in the way of glasses towards correcting this form of astigmatism, though much improvement of vision sometimes occurs when stenopaic spectacles are worn, the opening being made to suit the peculiarity of each case.

We now pass on to the much more common variety, which can frequently be exactly corrected by the help of plano-cylindrical lenses.

Regular astigmatism is due to the curvature of the cornea being different in the two meridians, that of maximum and minimum refraction; these are called

the *chief meridians*, and are always at right angles to each other.

In the normal eye the cornea is the segment of an ellipsoid and not of a sphere, so that there is a slight difference in the refraction of the two chief meridians, the focus of the vertical meridian being slightly shorter than that of the horizontal.

This can easily be proved by looking at a card on which is drawn two lines crossing each other at right angles; the card is held close to the eye and gradually made to recede; both lines cannot be seen at the same time with equal clearness, the horizontal being seen clearly at a shorter distance than the vertical line. So long, however, as the acuteness of vision is not impaired it goes by the name of normal astigmatism, or regular astigmatism of the normal eye.

Parallel rays passing through a convex spherical glass come to a focus at a point. If the cone of light thus formed be divided perpendicular to its axis, at any point between the lens and its focus, or beyond the focus after the rays have crossed and are diverging, a circle is formed. In astigmatism the case is different: if parallel rays pass through a convex lens which is more curved in the vertical than in the horizontal meridian, those rays which pass through the vertical meridian come to a focus sooner than those which pass through the horizontal; and the resulting cone, instead of being circular as in the previous case, will be more or less of an oval, forming a circle only at one point (4, Figs. 76 and 77). Let us now divide this cone at different points at right angles

to its axis, and notice the shape of the diffusion patches thus produced.

At 1, an oblate oval is formed; at 2, a horizontal straight line, the rays passing through the vertical meridian having come to a focus; at 3, 4, 5, the rays

FIG. 76.

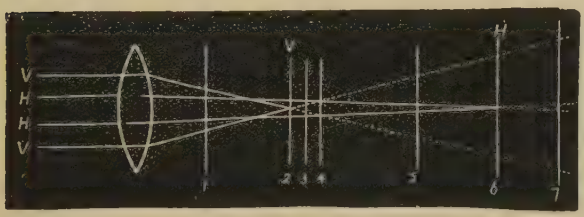


FIG. 77.

Section of cone of light at 1, 2, 3, 4, 5, 6, 7, Fig. 76.

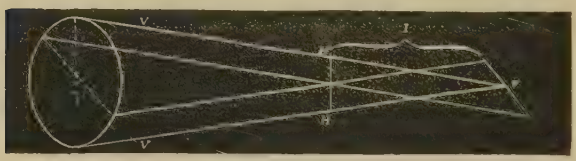
passing through the vertical meridian have crossed and are diverging, and the rays passing through the horizontal meridian are approaching; at 4 a circle is formed; at 6 a vertical straight line, the rays passing through the horizontal meridian have met, while those passing through the vertical meridian are still diverging; a large prolate ellipse is formed at 7.

The space between H and V, H being the point at

which the rays passing through the horizontal meridian focus, and v the point at which the rays passing through the vertical meridian meet, is called the interval of Sturm (1, Fig. 78).

Regular astigmatism was at one time thought to be due to defects in the curvature of the lens, but it has since been proved to depend almost entirely on

Fig. 78.



asymmetry of the cornea. The lens may, however, influence it in two ways:—1st. Its two chief meridians may not correspond to those of the cornea. 2nd. Owing to the position of the eye the lens may be situated obliquely.

It has been experimentally proved that slight amounts of corneal astigmatism may be corrected or disguised by the unequal contraction of the ciliary muscle (one segment of the muscle acting while the rest of the circle remains passive); the curvature of the lens is thus increased in the direction of the ciliary contraction only.

In astigmatism the vertical meridian of the cornea has usually the maximum, and the horizontal meridian the minimum of curvature, corresponding to the astigmatism of the normal eye, when this is so, we

speak of it as *astigmatism according to the rule*. To this, however, there are numerous exceptions. Thus the chief meridians may occupy an intermediate position, or the vertical may have the minimum, and the horizontal the maximum of curvature, then we have *astigmatism against the rule*. Whatever the direction of the two chief meridians, they are always at right angles to each other.

There are five varieties of regular astigmatism:

1. Simple hypermetropic astigmatism.
2. Compound hypermetropic astigmatism.
3. Simple myopic astigmatism.
4. Compound myopic astigmatism.
5. Mixed astigmatism.

In the first variety, one set of rays (we will assume the vertical, V) have come to a focus on the retina, while those at right angles, the horizontal (H), focus behind the eye. Thus, instead of a point, as in emmetropia, a horizontal straight line is formed on the retina, Fig. 79.

FIG. 79.

In the second variety, both sets of rays focus behind the retina, forming an oblate oval (Fig. 80).

In the third variety, one set of rays (we will assume the vertical) focus in front of the retina, the other set

on the retina, thus forming a vertical straight line instead of a point (Fig. 81).

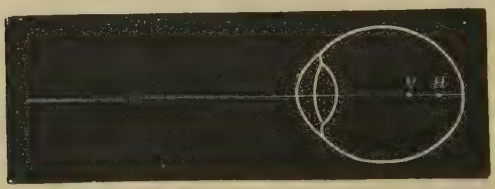
In the fourth variety, both sets of rays focus in

Fig. 80.

Fig. 81.

front of the retina, forming an upright oval (Fig. 82).

Fig. 82.



In the fifth variety, one set of rays has its focus in front, and the other set behind the retina (Fig. 83).

In these five figures, the focus of the vertical rays has been placed in front of the focus of the

FIG. 83.

horizontal rays; of course, it will be understood that the position of these two foci are frequently reversed.

From what has been said it will easily be seen, that when an astigmatic eye looks at a spot, it sees not a spot, but a *line*, an *oval*, or a *circle;* hence its name (*a* and *στίγμα*).

It is necessary that it should be thoroughly understood how the image of a line is formed on the retina: the clear perception of a line depends upon the distinctness of its edge, and to gain a clear image of this line it is necessary that the rays coming from a succession of points which make up this line (they of course emerge in every direction) should be brought to a focus on the retina, having passed through the cornea at right angles to the axis of the line. Should they not do so, circles of diffusion are formed, which overlap each other and so render the edges ill-defined. The rays which diverge from the line parallel with its axis, overlap each other on the retinal image, in-

creasing its clearness, except at the extremities, where they overlap and cause some slight indistinctness. Thus a person with simple astigmatism, myopic in the vertical and emmetropic in the horizontal, sees distinctly *vertical* lines, because the rays coming from the edges of the vertical line pass through the horizontal or emmetropic meridian, while those which come from the line parallel with its axis pass through the myopic meridian and overlap each other without causing any indistinctness of its edges. Therefore a patient with simple astigmatism sees clearly the line which is parallel with his ametropic meridian, and indistinctly the line parallel with his emmetropic meridian.

Causes:

1. Congenital malformation of the cornea, which may in astigmatism of high degree be part of a general malformation of the face and skull.

   This variety of astigmatism usually remains unchanged throughout life.

2. Operations involving the cornea or sclerotic, such as cataract extractions, iridectomy, etc.; these operations often cause by their cicatrisation a high degree of astigmatism, which changes considerably with time.

Symptoms.—There is frequently a want of symmetry about the patient's head or face. If young, and the astigmatism hypermetropic and of low degree, few symptoms may be present; usually, however, the patient complains of defective vision, with asthenopia,

especially if his work be such that his accommodation is in constant use; sometimes headache is a very marked symptom, either frontal or occipital; he has probably tried all sorts of spectacles, and can find none to suit him. On trying him at the distant type, his acuteness of vision is always below the normal, the mixed variety of astigmatism affecting it most, and next the compound. The way the patient reads the type may be an indication of the defect: he may be able to read certain letters better than others; thus he may decipher some letters of $\frac{6}{18}$ only, and yet be able to read some of $\frac{6}{12}$ and even some of $\frac{6}{6}$. We sometimes notice, when trying the acuteness of vision, that the patient sees much better if allowed to hold his head on one side; by doing this he places his nose somewhat in the line of vision of the eye he is using, and so cuts off some of the rays which would otherwise enter his pupils, thus diminishing his circles of diffusion. It is possible that if his chief meridians are oblique, by thus tilting them he brings them to correspond with the meridians of the object looked at. Whether this explanation be the correct one I know not, but we may generally feel pretty confident, when we see the patient looking at the test-type with his head on one side, that astigmatism is present. One frequently hears it said that images formed on the retina in astigmatism are distorted; this, however, is not the case, as can readily be proved by making one's own eye astigmatic, by placing in front of it a cylindrical glass: a certain amount of blurring and indistinctness is produced, but no actual

distortion, the distance between the cornea and retina being insufficient.

Usually both eyes are affected, sometimes quite symmetrically. Frequently, however, there is a great difference, one eye being almost emmetropic, the other very astigmatic.

In astigmatism, when the chief meridians of one eye are at right angles to the chief meridians of the other, binocular may be much better than monocular vision: we will illustrate this by a simple example. The right eye we will assume to be hypermetropic 2 D. in the vertical meridian, emmetropic in the horizontal; the left emmetropic in the vertical, hypermetropic in the horizontal 2 D. We know that the patient, looking at the fan of radiating lines with the right eye only, will see the vertical lines distinctly, the horizontal only by accommodating; with the left eye the horizontal lines will be clearly seen, the vertical ones indistinctly; with the two eyes all the lines will appear fairly distinct, the image in one eye overlapping that of the other. We seldom find a case in which the correction is so complete as in our example, but we meet with cases where partial correction takes place.

In my experience vision is less impaired when the chief meridians are vertical and horizontal than when they are oblique.

As hypermetropia is more common than myopia, so also is hypermetropic astigmatism of more frequent occurrence than the myopic variety, though few myopes will be found who are quite free from astig-

matism. Mixed astigmatism is the least frequently met with.

If, after trying the patient at the distant type, we are not satisfied with the result, though perhaps we have some improvement with either convex or concave glasses, we may suspect astigmatism and pass on to some of the special tests by which it may be diagnosed and estimated.

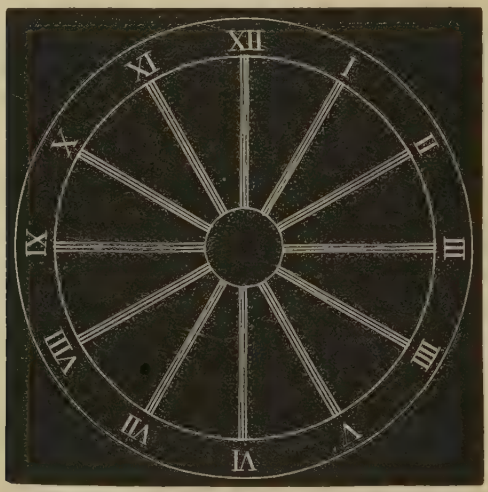
If astigmatism exist, our first object must be to find out the direction of the two principal meridians, viz. those of maximum and minimum refraction.

Most of the tests for astigmatism are based upon the principles of the perception of a line. An astigmatic eye looking at a test object composed of lines radiating from a centre, and numbered for convenience like the face of a clock, is unable to see all the lines equally clearly. The line seen most distinctly indicates the direction of one of the two chief meridians; the other chief meridian being of course at right angles to the one most clearly seen. The fan of radiating lines now very commonly used, as well as the clock face with movable hand, are all convenient test objects. The striped letters of Dr. Pray are useful for indicating one of the chief meridians.

To **test** and **measure** the astigmatism, we place our patient at a distance of six metres in front of the clock, Fig. 84, covering up one eye with a ground-glass disc. Supposing he see plainly the three lines from 12 to 6, all the other lines being more or less indistinct, those from 3 to 9 most so; and further, if

on placing before the eye a weak positive glass we find that lines from 12 to 6 are blurred, we know then

Fig. 84.



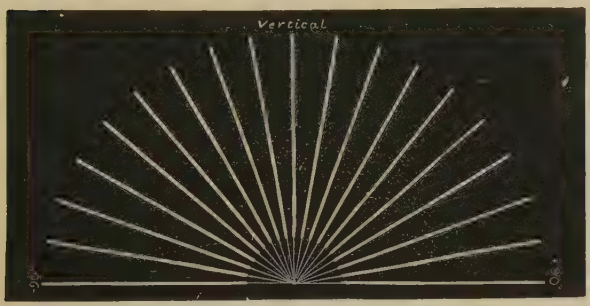
that the horizontal meridian—that is, the meridian at right angles to the clearly defined line—is emmetropic, as well as being one of the principal meridians. We now direct him to look steadily at the lines from 3 to 9, *i. e.* those at right angles to the lines first seen; we try what spherical glass enables him to see these lines distinctly and clearly; this glass is the measure of the refraction of the vertical meridian, and therefore also of the astigmatism.

To obtain reliable results, the eye *must* be thoroughly under the influence of atropine.

Supposing lines from 12 to 6 be clearly seen, but

that with a weak convex glass they are blurred; and that on looking at lines 3 to 9 no convex glass im-

Fig. 85.



proves their clearness, while — 1 D. renders them quite distinct, the case is one of simple myopic astigmatism.

With the ophthalmoscope the astigmatism may also be recognised. 1st. With the *indirect* method we find that the shape of the disc, instead of being circular, is more or less oval, changing its shape as the objective, which must be held exactly perpendicular, is withdrawn. 2nd. With the *direct* method we find that the disc appears oval, the long axis of the oval corresponding to the meridian of greatest refraction. Figs. 86 and 87 show the same disc as seen by the direct and indirect examination.

It is, however, the difference in degree of the clearness of the retinal vessels that is to be taken as the guide, not only of the chief meridians, but also of the kind and amount of error. To detect this, assuming

that the chief meridians are vertical and horizontal, we take notice first of the lateral margins of the disc,

Fig. 86.*

Erect image.

Fig. 87.

Inverted image.

and of a vessel running in the vertical direction, and find out the *strongest* positive, or the *weakest* negative glass, with which these are distinctly seen, using a refracting ophthalmoscope. We then take a horizontal vessel with the upper and lower margins of the disc, and estimate their refraction in the same manner. Thus a vessel going upwards is first taken; it is seen well with convex 1, the horizontal meridian therefore is hypermetropic 1 D. A horizontal vessel is now looked at, and can be best seen with concave 1, showing that the vertical meridian is myopic one dioptre;

* I have to thank Mr. Nettleship for these woodcuts from his work on 'Diseases of the Eye.'

the case is, therefore, one of mixed astigmatism. When the chief meridians are not vertical and horizontal, we must endeavour to find a vessel which coincides with one of the chief meridians, and having estimated this, we look for a vessel at right angles to that first chosen, and find out its refraction in the same way; this gives us the other chief meridian.

3rd. *Retinoscopy.* This is, I think, the easiest and most trustworthy of all the objective methods. The patient being fully atropised, the principal axes can be seen at a glance, and the proper glasses for correcting the error easily found by anyone who has taken the trouble to familiarise himself with this method of examination. For a full description of retinoscopy the reader must refer to Chap. V, p. 82.

Astigmatism requires for its correction a cylindrical glass, and reference has already been made to such a lens on p. 32.

This cylindrical glass is the segment of a cylinder; whereas a spherical glass is the segment of a sphere. The cylinder may be either concave or convex, and is numbered according to the refraction of the meridian of greatest curvature; the result upon rays that pass through it is, that those which pass through parallel to its axis undergo no refraction; all other rays are refracted, those most so which pass at right angles to the cylinder. A cylinder thus possesses the power of exactly neutralising the astigmatism.

On referring back to Fig. 79, which represents a case of simple hypermetropic astigmatism, the vertical meridian being emmetropic and the horizontal meri-

dian hypermetropic, it will be seen that a convex cylinder can be found, which with its axis vertical will increase the refraction of rays passing through the horizontal meridian, so that they meet exactly on the retina. Suppose the glass required be + 1 D. cylinder, this not only corrects, but is itself a measure of the astigmatism. If a patient with astigmatism of 1 D. be able to read $\frac{6}{12}$ of the distant type and with the cylinder + 1 D. axis vertical $\frac{6}{6}$, it may be expressed in the following manner: $\frac{6}{12}$ + 1 D. cy. axis vert. = $\frac{6}{6}$.

Fig. 80 represents compound hypermetropic astigmatism. We find out the refraction of each chief meridian by retinoscopy or the clock face. Assuming, then, the vertical meridian to be + 1 D., and the horizontal + 2 D., if we place our positive cylinder + 1 D. with its axis vertical, we shall have corrected the astigmatism, and the error will be reduced to one of simple hypermetropia, requiring for its correction + 1 D. sphere. This combination of sphere + 1 D. with cylinder + 1 D. axis vertical is made in one glass, by the optician grinding upon one side the sphere + 1 D. and on the other the cylinder + 1 D. The lens thus formed is called a spherico-cylindrical lens.

Fig. 81 represents simple myopic astigmatism, in which the vertical meridian is myopic and the horizontal emmetropic. To correct this error it is necessary to cause the rays which pass through the vertical meridian to be so refracted that they meet *at* instead of *in front of* the retina. Here it is obvious that a

negative cylinder with its axis horizontal will accomplish this object.

Fig. 82 represents compound myopic astigmatism. Both sets of rays focus in front of the retina, one set in advance of the other. This is corrected by carrying the focus back by a negative sphere, and so reducing the case to one of simple myopic astigmatism, which is corrected by a negative cylinder. This glass is called a negative spherico-cylindrical lens.

Fig. 83 represents mixed astigmatism. One set of rays focus in front of the retina, the other set behind it. The difference between these is the amount of astigmatism, and may be corrected in three different ways. Thus supposing the vertical meridian myopic 1 D., and the horizontal hypermetropic 1 D., the correction may be made by − 1 D. cylinder axis horizontal, which puts back the vertical rays so as to focus on the retina, combined with a + 1 D. cylinder axis vertical, which brings forward the horizontal rays to the retina. This compound lens is called a concavo-convex cylinder. There are, however, some difficulties in using this method of correction; the axes of the cylinders have to be arranged with such exactness, that the slightest variation may upset the whole result. Besides, it is difficult, when using such a combination at the distant type, to make alterations with the same facility with which one does other combinations. Moreover, during the grinding, very great care is required of the optician; so that either of the following plans seems preferable: by

a concave spherical glass of 1 D., combined with a convex cylinder of 2 D. axis vertical; or by a + 1 D. sphere, combined with − 2 D. cylinder axis horizontal.

Treatment.—Having found out by one of these numerous methods the refraction of the two chief meridians, we confirm the result by trying the patient at the distant type with the combination so found, making any slight alterations which may be necessary. These glasses may be ordered at once, remembering, when atropine has been used, that in hypermetropic astigmatism we must reduce the convex sphere about 1 D., while in the myopic variety the concave sphere must be slightly increased by about ·5 D.

We frequently have to be satisfied with glasses which do not raise the vision to $\frac{6}{6}$, and if such have been carefully chosen, we often find that after they have been worn for some time the vision improves, due no doubt to the retina becoming more sensitive to well-defined images, a condition of things to which it was previously unaccustomed.

In ordering glasses for astigmatism, we must be careful to give the exact axis of each cylinder: opticians supply us with convenient forms, having the diagram of a frame marked in degrees; we indicate the axis by drawing a line through this diagram.

The **Ophthalmometer of Javal** and **Schiotz** is an instrument for measuring the amount of corneal astigmatism. Scientifically it may be of much value, as by it we are enabled to separate astigmatism due to the cornea from that due to the lens; but the

price will prevent its coming into general use, especially as we possess so many other methods by which astigmatism may be estimated, and probably the separation of the two forms of astigmatism is a disadvantage practically, when we are seeking to correct the defect.

With the ophthalmometer two objects are reflected on to the cornea of the observed eye; these objects are of white enamel, one quadrilateral in shape, the other of the same size except that on one side it is cut out into five steps: these two objects slide on a semicircular arm, which rotates round the tube through which the observer looks, one object on either side of the tube; the observer looking through this tube, which contains a combination of convex glasses and a bi-refracting prism, sees four magnified images in a line on the cornea under examination. First find out the meridian of least refraction; this we are able to do by finding the position of the semicircular arm, in which the two central images (one quadrilateral, the other with steps) are furthest apart. We slide the two objects together until we see the two central images on the observed cornea just touch, the lowest step of the one with the side of the other; this, then, is the meridian of least refraction, and we note it down as such. Now turn the arm at right angles to this meridian, and notice the amount of overlapping of the two central images; each step in the one figure that is overlapped by the quadrilateral one is equal to one dioptre. Thus if it overlap three steps, there is a difference of 3 D. between

the meridians of least and greatest refraction; we know this to be the meridian of greatest refraction, because it is at right angles to the one first found.

As there are only five steps, when there is a difference of 5 D. between the two meridians, the one figure will exactly overlap the other: for higher degrees we have to calculate how much the figure with the steps projects beyond the quadrilateral figure; or we may place in the tube a stronger bi-refracting prism, then each step may be counted as two dioptres instead of one.

Nordenson has obtained some interesting statistics with this ophthalmometer ('Ophthalmic Review' for July, 1883) in 226 school children. As a result of these statistics he is of opinion—

1st. That the correction of corneal astigmatism by means of the lens in young persons is the rule.

2nd. That corneal astigmatism amounting to one and a half dioptres is incompatible with normal acuteness of vision.

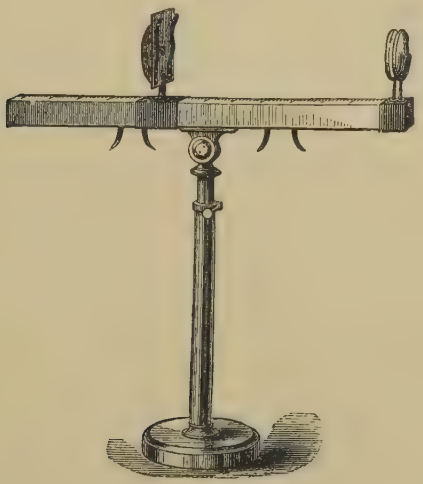
Nordenson's observations agree with the opinion expressed by Javal that astigmatism predisposes to myopia.

Tweedy's Optometer affords an easy method of estimating the refraction in astigmatism. It consists essentially of a plate carrying the figure of a dial marked with fine dark radiating lines at angles of 15° with each other; the plate is attached to a horizontal bar half a metre long, divided into centimetres, on which it may be made to slide: at the proximal end of the bar is a semicircular clip, marked with degrees

corresponding to those on the dial, and intended to hold the cylindrical lens. In order to use the instrument properly, the following instructions must be strictly complied with:

1st. The eye about to be examined having previously been placed completely under atropine, and made artificially myopic to about 4 D. by means of a

Fig. 88.



strong convex lens placed in a spectacle frame, and the opposite eye excluded by an opaque disc, the patient should sit down before the instrument, place the eye with the lens before it close to the clip, and with the head erect should look straight in front at the radiating lines of the dial.

2nd. The dial having first been removed beyond the point of distinct vision, should then be gradually

approximated along the bar, until at least one of the lines is clearly and distinctly seen; after this the dial should on no account be moved, but its distance from the eye accurately noted.

If all the radiating lines come into view with equal clearness at the same time there is but slight astigmatism; but if whilst one line is clearly seen, that at right angles to it is blurred, there is astigmatism, which may be corrected by placing in the semicircular clip a concave cylindrical lens with its axis parallel to the blurred line, or at right angles to that first distinctly seen.

From the result of (2) we learn (*a*) the direction of the two principal meridians, of maximum and minimum refraction; (*b*) the presence or absence of hypermetropia or myopia, and the degree; (*c*) the presence or absence of abnormal regular astigmatism, including its direction and degree. (*a*) The meridian of greatest refraction is parallel to the line seen at the greatest distance of distinct vision, while the meridian of least refraction is always at right angles to it. (*b*) The presence or absence of ametropia is determined by the distance at which the radiating lines are clearly seen. If there be emmetropia, the lines will be seen exactly at the distance of the focal length of the lens employed to produce the artificial myopia: if there be hypermetropia, the lines will be seen beyond that point; if myopia, within. The degree of ametropia may be estimated by the following calculation. The greatest distance of distinct vision, *minus* the focal length of the lens, divided by

the multiple of these numbers, equals the degree of ametropia.

(*c*) If, however, there be astigmatism, the above calculation will give the refraction for the meridian of least refraction only; the degree of astigmatism will be represented by the focal length of the weakest concave cylinder, which, placed with its axis parallel to the blurred line, makes this line as clear and distinct as that first seen. The whole ametropia may then be corrected by combining the spherical lens required for the correction of the meridian of least refraction, with the weakest cylindrical lens which by actual experimentation has been found sufficient to correct the astigmatism.

Placido's disc consists of a circular sheet of tin on which is painted concentric circles of black and white; it enables one to detect the chief meridians of the cornea at a glance. The patient being placed with his back to the light is directed to look at the centre of the disc, while the observer, holding the instrument close to his own eye and at a convenient distance from the patient's, looks through the hole in its centre; he sees an image of the concentric circles reflected on the cornea: if astigmatism exist, the rings will appear elliptical, with the long axis corresponding with the meridian of least curvature. Cases of irregular astigmatism and conical cornea are easily detected by this method.

The **stenopaic slit**, which consists of a metal disc having an oblong opening in it about 2 mm. broad, is used by some observers for working out cases of

astigmatism. The disc is placed in a trial frame in front of the eye we wish to examine; and while the patient looks steadily at the distant type the disc is slowly rotated, so that the slit is brought successively in front of each meridian, the position in which the best vision is obtained is noted; we then try convex and concave spheres in front of the slit, to see if any improvement take place. The slit is now in line with one of the chief meridians; let us turn the disc round 90°, so that the slit may occupy the position of the other chief meridian, and find out what sphere most improves vision. Thus, supposing with the slit in the vertical direction the patient reads $\frac{6}{6}$, while convex glasses in front of the slit make it indistinct, the vertical meridian is emmetropic; and on turning the slit so that it is horizontal, the patient reads $\frac{6}{12}$, but with + 2 D. sphere the vision equals $\frac{6}{6}$, the horizontal meridian is then hypermetropic, and the case is therefore one of simple hypermetropic astigmatism, requiring for its correction + 2 D. cylinder axis vertical. On looking through the slit, placed between the principal meridians, circles of diffusion are formed, and the object has the appearance of being drawn out in the direction of the slit.

Dr. Tempest Anderson, of York, has invented an ingenious instrument by which astigmatism may be estimated in a subjective manner; an image of an illuminated radiating screen is thrown on the retina, and is visible to the observer; the position of the screen on a graduated bar shows the refraction.

The inventor claims for his instrument the following advantages:

1. The observations and measurements are made by the observer, and are entirely independent of the patient's sensations, though these may be used as an adjunct if wished.

2. An image thrown on the retina being used as an object, the error arising from the vessels or optic nerve being before or behind the retina is avoided.

3. The refraction and accommodation of the observer does not affect the result. It is only necessary that he should be able to see whether certain lines are sharply defined.

In addition to the methods already described for estimating astigmatism, many others are known.

See Cases 3, 4, 5, 6, 7, 8, 9, p. 110, &c.; also 20 and 21, p. 254.

Anisometropia

Anisometropia (ἀ, priv.; ἴσος, equal; μέτρον, measure; ὤψ, the eye) is the term applied to cases which frequently occur, where the two eyes vary in their refraction. The defect is usually congenital, but it may be acquired, as in aphakia or loss of accommodation in one eye. Every possible combination may exist: one eye may be emmetropic, the other myopic or hypermetropic; or one more myopic, hypermetropic, or astigmatic than the other.

Anisometropia may be met with under three chief forms:

1. Cases where binocular vision is present.
2. When the eyes are used alternately.
3. One eye is permanently excluded from vision.

1. In the first variety the difference in refraction is usually not very great; and if it were possible for the patient to accommodate unequally in the two eyes, he might be able to obtain clear images on each retina; but it is probable that the two ciliary muscles make the same effort, with the result that in one eye the image is well defined, in the other indistinct.

2. When the eyes are used alternately, then one eye is usually emmetropic or hypermetropic, and is employed for distant vision; while the other is myopic and is used for near work.

3. When the difference between the two eyes is very great the best eye may be used exclusively, while the vision in the other is very bad, and frequently

deviates outwards or inwards; in many of these cases one eye is emmetropic or slightly hypermetropic, the other highly myopic.

Treatment.—When the difference is not very great (1 or 1·5 D.), and vision in both eyes is good, we may give each eye its correction for constant use: for so long as the eye whose refraction is the more defective still co-operates in binocular vision, sight is improved thereby. Especially is this full correction useful in cases of myopia with divergent strabismus, the increased stimulus to binocular vision being sometimes sufficient to prevent the squint.

Many cases do not stand their full correction for each eye with comfort; they complain of strain, discomfort, and headache, though the younger the patient the less liable is he to suffer from these symptoms.

The asthenopia which often results from giving each eye its exact correction may possibly be due to the different prismatic effect which must result when the patient looks obliquely through his two glasses which have a different refractive power, and it has been suggested by Mr. W. A. Dixey to overcome this difficulty by using a bifocal lens before the eye whose refraction is more defective. This can be done by grinding a small central portion of the glass—that, in fact, which is immediately in front of the pupil—of such a focus as to fully correct the error, while the other part of the lens will be ground of the same focus as the glass in front of the less defective eye. Thus, to take an example, a patient has 4 D. of myopia in the right eye and 2 D. in the left; for the right eye

he would require a glass which was − 4 D. in the centre, — 2 D. at the margin, while the left eye would be supplied with − 2 D.

When one eye is emmetropic and the other myopic, no glass will probably be required, the emmetropic eye being used for distance, the myopic eye for reading, &c. When the difference in the refraction is greater than 1·5 D. we may have to be satisfied with partially correcting the difference, and this result can only be arrived at by trying each case, some people tolerating a much fuller correction than others, our object being to give as near as possible the full correction for each eye. When binocular vision does not exist, frequently no attempt can be made to correct the two eyes, and then we generally give glasses that suit the best eye. In cases of aphakia, &c., where one eye is used almost entirely, while the other, though defective, still possesses vision, it is an excellent plan to insist on the latter being daily exercised with a suitable glass, the good eye being at the same time covered ; by this means the bad eye is prevented from becoming worse, and can at any time be utilised should occasion require.

See Cases 14 and 15, pp. 248 and 251.

CHAPTER IX

PRESBYOPIA. Pr. (πρέσβυς, old; ὤψ, eye)

With advancing age many changes take place in the eye. The acuteness of vision becomes less, owing partly to a loss of transparency in the media, and partly to a diminution in the perceptive and conductive powers of the retina and the optic nerve. At the age of forty the acuteness of vision is almost unaltered, the bottom line of the distant type being read at a little over 6 metres; at fifty it can still be read at 6 metres, but after this time it diminishes regularly, so that by the eightieth year vision may have decreased to $\frac{6}{9}$ or $\frac{6}{12}$. In addition to these changes, the *accommodation* gradually diminishes from a very early period, the near point slowly but steadily receding. This change in the accommodation occurs in all eyes, whatever their refraction, and is due to an increased firmness of the lens, whereby its elasticity is lessened; and perhaps also in some slight degree to loss of power in the ciliary muscle due to advancing age. The lens also approaches the cornea, and becomes somewhat flatter. This failure of the accommodation begins as early as the tenth year, at an age when all the functions of the body are still developing.

Presbyopia must therefore be looked upon as a physiological condition.

When the binocular near point has receded beyond the distance at which we are accustomed to read

Fig. 89.

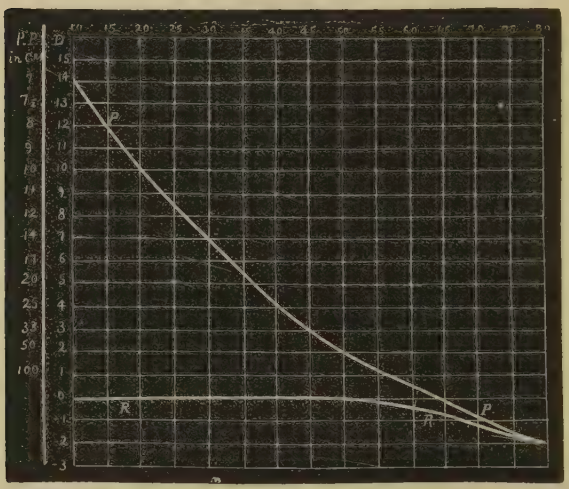


Diagram showing the course of accommodation in an emmetropic eye. The figures at the top of the diagram indicate the age; those at the side the amount of accommodation and the p. p. in centimetres; the oblique line represents the course of the punctum proximum, and the horizontal line that of the punctum remotum; the space between the two lines gives the amplitude of accommodation. From this diagram we can calculate the amplitude of accommodation possessed at any age.

and write with comfort, we become restricted in our work. Donders has fixed this point at 22 cm.

Presbyopia, therefore, may be arbitrarily stated to exist when the binocular near point has receded to 22 cm., and this occurs usually in the emmetrope about the age of forty-five. Because in order to see at 22 cm., a positive refractive power of 4·5 is necessary ($\frac{100}{22} = 4{\cdot}5$); at the age of forty, the eye possesses just this amount of refractive power; but if the eye has not so much accommodation, then we must give such a convex glass which, added to it, brings up the positive refraction to 4·5 D.: for example, at the age of fifty-five, when the eye possesses only 1·5 D. of accommodation, we give a convex glass of 3 D., because 1·5 D. + 3 D. = 4·5 D. (see table, p. 191).

To find the punctum proximum of an emmetrope, we have only to divide the number of dioptres of accommodation which he possesses into 100 cm. Thus at twenty there are 10 D. of accommodation; this would give us 10 cm. as the near point. At forty there are 4·5 D., in which case the near point is 22 cm.

When the punctum proximum has receded to 22 cm., the point at which it is convenient to read is considerably further away, since for sustained vision only about half of the accommodation can be used. Thus a person with 4 D. of accommodation would have his near point at 25 cm. with the maximum contraction of his ciliary muscle, and if he can only comfortably use about half this for continuous work, his reading point would be 50 cm.; this is too great a distance. We bring back the near point by convex

glasses, which is practically the same as increasing the accommodation.

Although we have said that only about one half of the accommodation can be used for sustained vision, this is not absolutely correct: the amount which must be in reserve varies much with different individuals; thus in one case with a surplus of 1 D. much work can be done, whereas in another a surplus of 3 or 4 D. is necessary.

Symptoms.—The presbyope sees well at a distance, but has difficulty in maintaining clear vision for near objects; the chief symptoms are a feeling of weariness in the eyes after reading, especially in the evenings, small objects being less easily seen than formerly, because, having to be held further from the eyes, they subtend a smaller visual angle. The patient seeks a strong light, or places the lamp he is using between his eye and the book; by doing this he causes his pupils to contract, and so lessens his circles of diffusion; he avoids small print, and holds the book or work further away. These symptoms are due to a recession of the near point, and if asthenopia occur, this may be dependent upon a disturbance of the balance between accommodation and convergence; the convergence being the same for any given point, a much greater accommodative effort is necessary than was formerly the case.

The **treatment** of presbyopia consists in prescribing convex spectacles for reading and near work, so as to bring back the near point to a convenient distance. The best reading distance for a person with normal

visual acuity is from 30 to 40 cm.; most emmetropes will, therefore, require a convex glass for near work soon after the age of forty-five; we have only to remember to add on + 1 D. for every five years until we have reached + 3·5 D.

An emmetrope with good visual acuity will never require a stronger glass than + 3·5 D. even when sixty or seventy years of age, because these glasses adapt him for a distance of 30 cm. without any accommodation.

Should the patient have defective vision, then it may be necessary for him to hold near objects much closer to the eyes than 30 cm. in order that he may get larger retinal images; here we should be justified in prescribing much stronger glasses.

The following table gives approximately the strength of glasses required by emmetropes at different ages to bring back their punctum proximum to 22 cm.:

Age.	Amount of accommodation possessed at that age.	The near point.	Glass required to bring back p. p. to 22 cm.
45	3·5 D.	28 cm.	+ 1 D.
50	2·5 D.	40 cm.	+ 2 D.
55	1·5 D.	67 cm.	+ 3 D.
60	·5 D.	200 cm.	+ 4 D.
70	·0 D.	infinity	+ 4·5 D.

It must be understood that this table indicates the glass that brings the p. p. back to 22 cm., and if we wish the patient to read at 33 or 40 cm. these glasses will in practice be found too strong.

To find the glass required in presbyopia, we substract the glass which represents the receded near point, from the glass whose focus represents the point

we wish to make the near point. Thus the near point has receded to 50 cm.; the glass representing this point is + 2 D. ($\frac{100}{50} = 2$). We wish to bring the near point to 25 cm.; this would be + 4 D. ($\frac{100}{25} = 4$); hence + 2 D. from + 4 D. gives + 2 D. as the glass required.

Although glasses can be frequently thus ordered by a sort of rule of thumb, it is always well to bear in mind that the definition given of presbyopia with reference to its near point is entirely an arbitrary one, and that we must take into account the distance at which the individual has been accustomed to read and work. In this there is great variety. Many small people work and read at 25 cm., whereas very tall people may be uncomfortable unless the book they are reading is 35 or 40 cm. away. The distance for which the presbyope requires spectacles will also vary much according to the occupation for which he requires them; thus a carpenter sixty years old with emmetropia may require to work at his bench, which may be at one metre away; to enable him to see at this distance he will require + 1 D., while for reading at 33 cm. he will require + 3 D.

There exists a popular prejudice against the use of strong glasses, all sorts of maladies having been attributed to their use. This prejudice is quite unfounded; if the lenses are too strong they may bring the reading point inconveniently near, and so produce asthenopia by causing the patient to converge excessively.

Before ordering glasses for presbyopia, always try the patient's distant vision, so that any hyper-

metropia or myopia may be recognised. If hypermetropia exist, the amount must be added to the presbyopic glass; if myopia, it must be subtracted. Thus a patient with hypermetropia requiring + 2 D. for its correction, at the age of forty-five will require + 3 D. for reading (H. 2 D. + Pr. 1 D. = + 3 D.).

A myope of 1 D. will require no glass at the age of forty-five (M. 1 D. + Pr. 1 D. = 0). If the myopia be 3·5 D., then the patient can never require a glass for presbyopia, his far point being 30 cm. always. His near point may recede to this distance when all accommodation is lost, but he will still be able to read at that distance, though at that distance only.

But allowance must be made for the fact that as age advances the refraction of the eye diminishes; in other words, the eye if emmetropic becomes hypermetropic (called acquired hypermetropia). The myopic eye becomes less myopic, so that a real improvement in vision takes place. The hypermetropic eye becomes more hypermetropic. This change takes place at a regular rate in all eyes; at fifty-five the refraction has diminished ·25 D., at sixty-five ·75 D., at sixty-eight 1 D., and at eighty as much as 2·5 D. Thus at eighty an emmetrope will have acquired 2·5 D. of hypermetropia, and will therefore require a convex glass + 2·5 D. for distant objects to be seen clearly. A myope of 2·5 D. would at eighty have become emmetropic, and require no glass for distance. A hypermetrope of 2·5 D. will add on to his defect 2·5 D., and will require a + 5 D. for distance. This change

is due to sclerosis and enlargement of the crystalline lens, by which its refractive power is diminished.

Dr. Scheffler some years ago proposed the use of what he called orthoscopic lenses, that is, lenses with two elements, a sphere and a prism, so proportioned that the amount of accommodation and convergence should exactly correspond. Thus in the case of a presbyope aged fifty, requiring + 2 D. to make him read comfortably at 25 cm., it would be combined with a prism of 2 m.a. base inwards, the result being that the patient would then have to put on 2 D. of his accommodation and 2 m.a. of convergence, and thus these two functions would be used in equal degrees. The results, however, are not so good as might have been hoped; the glasses are too heavy, and on looking at a flat surface some distortion is produced. Nevertheless cases do occur in which, though the presbyopia is corrected, the patient after reading a short time complains of asthenopia. Such cases are frequently at once and completely relieved by combining with the spheres, prisms of 2° or 3° with their bases inwards; or by having the lenses decentred, forming convex prismo-spheres (Fig. 101).

A lens of 1 D. must be decentred 8·7 mm. to produce a prismatic effect of 1°. Thus in order to find out the amount that a lens should be decentred to produce a given prismatic effect, it is necessary to multiply 8·7 by the number of the prisms we wish to use, and divide the result by the number of the lens. Thus, to take an example, with a + 6 D. we wish to produce a prismatic effect of 2°, then

$\frac{8{\cdot}7 \times 2}{6} = \frac{17{\cdot}4}{6} = 2{\cdot}9$ mm.; the glasses would require to be decentred inwards 2·9 mm.

Care must be taken to see that the glasses are properly centred, unless they have been ordered otherwise; for if the frames are too broad, the prismatic effect produced is very apt to give rise to asthenopia, by disturbing the relations between convergence and accommodation.

In cases where the convex glasses have frequently to be changed for stronger ones, "glaucoma" should be carefully looked for; and if any symptoms of it appear, no near work must be allowed, as it is important to avoid all possible causes of tension.

The commencement of cataract may in some cases hasten presbyopia, but it more frequently produces myopia, so that the presbyope requires his glasses diminished in strength.

In each case of presbyopia first test the patient's distant vision, so as to detect any hypermetropia, myopia, or astigmatism; and having recorded this, we add the glass which he requires for his presbyopia and try him with the reading type: should they suit, we direct the patient to read with them for half an hour or so; if found satisfactory we order spectacles of this strength.

See Cases 12, 16, 17, and 18, p. 247, &c.

Paralysis of the Accommodation

Paralysis of the accommodation, either partial or complete, arises from loss of power in the ciliary

muscle (cycloplegia), and is due to paralysis of the third nerve, or of that branch of it which supplies the muscle of accommodation and the circular fibres of the iris. Cases do occasionally occur, though very rarely, of paralysis of the ciliary muscle not involving the constrictor pupillæ. Both eyes may be affected, or only one.

When the paralysis is confined to the ciliary muscle and iris, it goes by the name of ophthalmoplegia interna.

Causes.—Atropine is the most common cause, but it may be due to diphtheria, rheumatism, fever, any complaint of a lowering character, cerebral trouble, syphilis, diabetes, or some reflex irritation, *e.g.* decayed teeth, &c.; the cause may, however, not be apparent. When the whole third nerve is involved, ptosis, external strabismus, &c., occur; but in those cases where the branch supplying the ciliary muscle and the circular fibres of the iris is alone implicated, the indicating symptoms are asthenopia, dilatation of the pupil, and loss of the power of accommodation, whereby the patient, though able to see distant objects well (if emmetropic), is unable to read or do any near work. If hypermetropic, both near and distant vision will be impaired; if myopic, he is able to see only at his far point. We try the patient at the distant type, and if he is able to see $\frac{6}{6}$ and yet is not able to read near type, the diagnosis is obvious.

Treatment consists in giving such convex glasses as enable him to read. In order to bring the emmetrope's far point from infinity to 33 cm., + 3 D. is

required ($\frac{100}{33}$ = 3). We must bear in mind that by encouraging the action of the ciliary muscle we hasten the patient's recovery; we therefore order the *weakest* convex glasses with which he is able to read, changing them for weaker ones occasionally as the ciliary muscle gains strength. Sulphate of eserine in solution, gr. j to ℥j, causes contraction of the ciliary muscle as well as of the iris, and temporarily relieves the symptoms. I think much good sometimes results from its use once every other day for some weeks; the ciliary muscle being made to contract, relaxing again as the effect of the myotic passes off: sometimes the local application of electricity is useful. Attention must be paid to the general health, iodide of potassium or nerve-tonics being given when indicated by the cause.

See Case 13, p. 248.

Spasm of the Accommodation

Spasm of the accommodation may be of two kinds, *Tonic* and *Clonic*.

Clonic spasm occurs only when the eye is in use, ceasing as soon as it is in a condition of repose.

Tonic spasm is more permanent, requiring atropine or one of the other mydriatics for its relief; the expression *spasm of accommodation* usually refers to this variety of the disorder.

Tonic spasm of the ciliary muscle may be occasionally met with in eyes whatever their refraction,

though most commonly in cases of hypermetropia and low myopia; it has the effect of increasing the refraction of the eye, and is found most frequently in children.

Causes.—It may occur as a result of uncorrected ametropia, or in emmetropia from overwork, especially when such work has been done in a bad light; as a result of contusion of the eyeball, and sometimes it occurs with cyclitis.

Symptoms.—It usually affects both eyes, giving rise to symptoms of asthenopia with a feeling of constriction and discomfort in the eyes themselves; there may be an increased secretion of tears with or without blepharospasm; the acuteness of vision may be diminished and is very variable, while the size of the pupil usually remains unaffected. In emmetropia we may get symptoms of myopia, owing to the parallel rays coming to a focus in front of the retina. In hypermetropia the symptoms may also simulate myopia, and for this we should always be on our guard. I have on several occasions seen hypermetropes going about wearing concave glasses to correct their supposed short-sightedness. Some time ago I saw a young man who had worn — 7 D. constantly for years, though his refraction was really emmetropic. In myopia the real defect is apparently increased, and we might be in danger of ordering too strong concave glasses, &c. For these reasons the systematic use of atropine in young people (whereby one is enabled to estimate and record the exact state of the refraction) cannot be too strongly insisted upon.

The **treatment**, where spasm of the ciliary muscle is suspected, is to drop into the eyes three times a day a solution of sulphate of atropine, grs. iv to ℥j, for two or three weeks; this quickly relieves the spasm, and gives the eyes complete rest: any ametropia that may exist must be corrected, and the patient's general health attended to, tonics being administered if necessary.

A few cases of acute spasm of the accommodation have been recorded which resisted the treatment by atropine; the spasm, though relaxed by this means, returned as soon as the atropine was discontinued.

See Case 1, p. 110.

CHAPTER X

STRABISMUS [στρέφω, I turn aside]

STRABISMUS exists when there is a deviation in the direction of the eyes, so that the visual axes are not directed to the same object.

Strabismus may be divided into two classes—

Concomitant.

Paralytic.

Concomitant strabismus is a frequent result and complication of refractive errors, and has already been referred to on pages 124 and 146.

The deviation of one eye from its correct position is the result of disturbed muscular equilibrium, and may be due to—

1. Defective anatomical conditions, or
2. Abnormal innervation causing contraction of the muscles not in accordance with the requirements of binocular vision. Most cases of concomitant strabismus are due to this second cause.

The points to note when a case of strabismus presents itself are—

1. Is the strabismus real or only apparent?

2. If real, to which variety does it belong ?
3. Which is the deviating eye ?
4. In which direction is the deviation ?
5. What is the degree of the deviation ?
6. What is the cause of the strabismus ?

The first of these questions may seem unnecessary, but it is not always easy to say if squint is really present or not, because one judges of the direction of the eyes by the position of the centres of the corneæ, or rather by the optic axes, and these may diverge slightly while the visual axes are really parallel. This requires some explanation.

The visual axis is the line passing from the macula through the nodal point to the object looked at, shown in the following figures as V M.

Fig. 90.

The optic axis is the line passing through the nodal point and the centre of the cornea to the inner side of the macular, O H in figures.

It will thus be seen that these two axes form an angle at the nodal point which in emmetropia amounts usually to 5° (Fig. 90).

This is called the angle *a*, and when thus formed

by the crossing of the visual and optic axes it is said to be *positive*.

In hypermetropia (Fig. 91) the angle *a* increases

Fig. 91.

with the degree of hypermetropia, and if it be high may attain 7°, 8°, or even more; this large angle gives to the eye an appearance of divergence.

Fig. 92.

M. The macula. N. The nodal point. B. Optic nerve. V. The object. V M. The visual axis. O H. The optic axis. *a*. The angle alpha formed between the visual and optic axes. C. The centre of rotation of the eyeball situated on the optic axis. γ. The angle gamma (Fig. 90) is formed at the centre of rotation of the eyeball, by the optic axis and a line drawn from the centre to the object looked at.

In myopia (Fig. 92) the angle *a* decreases, and in high myopia the visual axis may approach the optic

axis, so that the angle α is very small, or it may coincide with it when no angle is formed; or even be altogether on the outer side of it, when the angle is said to be *negative*. This small angle α gives to the eyes an appearance of convergence.*

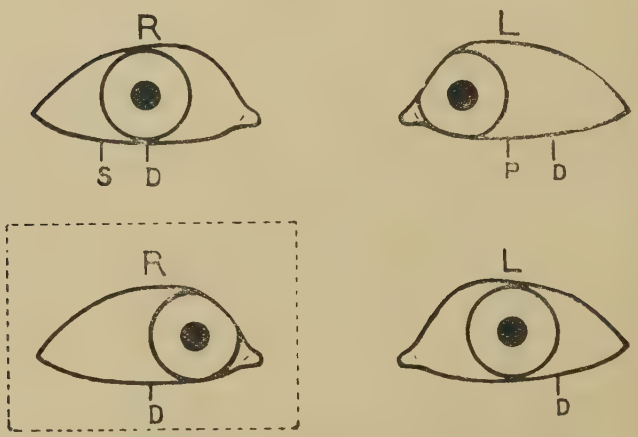
In order to find out the variety to which our case of strabismus belongs, as well as to decide which is the deviating eye, we direct the patient to look at an object held about a metre in front of him, then gradually bring this object nearer to him, so as to call into action the accommodation: if both visual axes continue to be directed steadily towards the object as it is made to approach the eyes, the case is one of *apparent* strabismus; but if one eye fix the object while the other, after following it up to a certain distance, suddenly deviates inwards or outwards, the condition is spoken of as *concomitant* strabismus (convergent or divergent); or both eyes may follow the object up to a certain point, when one stops, after perhaps making a few jerking oscillating movements; it then belongs to the *paralytic* variety of strabismus.

Again, direct the patient to look at some object held midway between the two eyes and about a metre away; if the right eye fix the object while the left deviates inward, we mark upon the edge of the lower lids with a pen the position of the external margin of

* Another angle sometimes mentioned is the angle γ, which is the angle formed at the centre of rotation of the eye by the optic axis and a line drawn from this centre to the object looked at, shown in Fig. 90.

the cornea in each eye, S and P: on covering the right eye with a card, the left will at once make a

FIG. 93.



The two upper diagrams, R and L, show the primary position of the eyes, the right being the fixing eye, while the left is deviating inwards. On covering the right eye with a card, as shown by the dotted lines, the left eye fixes while the right deviates inwards. P D therefore indicates the primary deviation, S D the secondary deviation.

movement outwards to fix the object, and we make a second ink mark, D, on the lids corresponding with the outer edges of the cornea in this position.

The distance P D gives us the amount of *primary deviation;* it may further be seen that on covering the right eye so as to cause the left eye to fix the object looked at, the right eye has made a movement inwards behind the screen, a *secondary deviation* has taken

place, this is recorded by an ink mark on the right lower lid at D; we have thus found the linear measurement of the secondary deviation, S D.

The primary deviation (P D) will be found to equal the secondary deviation (S D), a characteristic of concomitant squint.

In paralytic squint the secondary deviation is always greater than the primary.

This variety of squint is known as *concomitant*, because the squinting eye follows the fixing one in all its movements, the amount of squint always being the same whatever be the direction in which the eyes are turned; therefore the range of movement in concomitant squint is as great as in cases where no squint exists; it is simply displaced. In the paralytic form, the movements of the squinting eye are usually much curtailed; this we easily detect by holding up the finger about 50 cm. in front of the patient, and directing him, while keeping the head still, to follow the movements of the finger, which is moved to either side, then up and down.

So that in concomitant strabismus the squinting eye will almost exactly accompany the other, the visual lines being at the same angle, except perhaps in the extreme periphery, whereas in the paralytic variety one eye will stop at a certain point, while the other eye continues to follow the finger.

Concomitant squint is characterised by the fact that the primary and secondary deviations are equal; in paralytic strabismus the secondary deviation exceeds the primary; in paralytic squint the diplopia is

the most prominent subjective symptom, while in the concomitant variety it is seldom complained of.

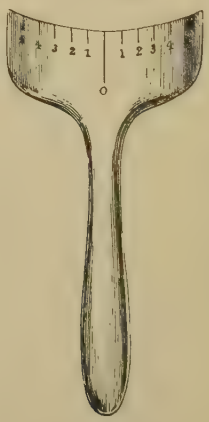
When either eye fixes indifferently, the vision being equally good in both, the strabismus is *alternating;* when the same eye always squints, it is *monolateral* or *constant*. The vision in the squinting eye is often below that in the fixing one.

Periodic is the name applied to the squint when it only comes on occasionally, as after looking for some time at near objects. With judicious treatment this variety can be cured without operation; if neglected it generally passes on into one of the constant forms.

There are several ways by which the amount of the deviation may be estimated. Thus we may record it in the form of a diagram (Fig. 93).

The strabismometer (Fig. 94) consists of a handle

FIG. 94.



Strabismometer.

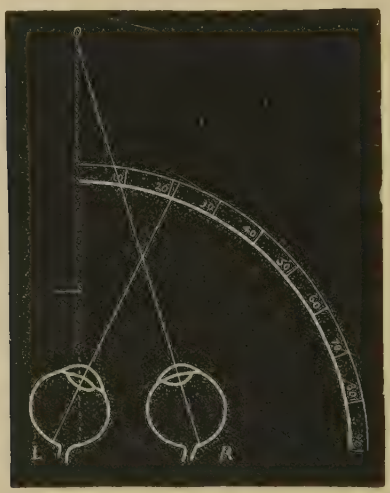
supporting a small ivory plate, shaped to the lower lid, and having on it a scale by which we measure the amount of deviation of the centre of the pupil. This is an easy method of measuring the strabismus, but is not to be depended upon.

The measurement of the *angle of the strabismus* is the only reliable and exact method of recording the amount of squint, and is the method therefore recommended. The angle of the strabismus may be defined as that angle which the visual axis makes with the direction it should have in a normal state.

For this measurement we require a perimeter, in front of which we seat the patient, with the quadrant placed according to the kind of squint we are about to measure; if it be convergent or divergent, then the quadrant is placed horizontally. The patient being seated so that his deviating eye is in the centre of the instrument, we direct him to fix with both eyes some distant object (o, Fig. 95) placed in a line with the centre of the perimeter; a lighted candle is moved gradually along the inside of the quadrant from the centre of the instrument outwards; the observer, following the movement of the candle with his head, stops as soon as the reflection of the candle on the cornea of the squinting eye occupies the centre of its pupil, this gives the direction of the optic axis; what we really wanted was the direction of the visual axis, but for all practical purposes the former is sufficient. The degree is read off the quadrant at the point where the candle was stopped, and this result recorded. The angle of deviation for near vision

should next be taken; this may be done by requesting the patient to look at the centre of the perimeter,

Fig. 95.*



proceeding with the candle as before, and recording the result.

Concomitant strabismus is intimately connected with hypermetropia and myopia; it may be—

Convergent

or

Divergent.

Convergent Concomitant Strabismus.—On looking at any object, one eye only is directed to it; the other,

* In the above diagram, o is intended to represent a distant object; it is placed near the perimeter in order to take up less room.

as the name implies, turns inwards so that the angle of convergence is much greater in the deviating than in the fixing eye.

The common cause of this variety of squint is hypermetropia, at least 80 per cent. of the cases are due to this cause; its method of production depends upon the intimate connection that exists between accommodation and convergence.

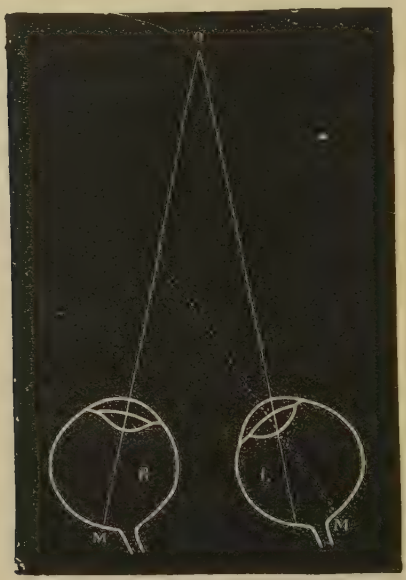
The convergence is most marked when looking at near objects; sometimes there may be no squint when distant objects are viewed.

A person who is hypermetropic requires to use some of his accommodation for distance; for near objects he must, of course, use still more, and for every increase in the accommodation there is a desire for an equal increase in the degree of convergence. Thus an emmetropic individual, accommodating for an object at 30 cm., would at the same time converge for that particular point.

If the individual were hypermetropic to the extent of 4 D., and supposing the amplitude of his accommodation amounted to 8 D.; then he would require to use half this (4 D.) to enable him to bring parallel rays to a focus on the retina; and he would have the tendency at the same time to use 4 metre-angles of convergence. Thus for distant objects he would have an inclination to converge, his internal recti acting; and it is only by the increased tension of the external recti, called into action by the desire which all eyes possess for singleness of vision, that convergence is prevented. The more we accommodate the greater

is the stimulus to converge, so that on looking at near objects—which necessitates an increase of the accom-

Fig. 96.



R. Right eye directed to object O. L. Left eye deviating inwards. M. Macula.

modation—an increased tendency to convergence is produced.

Now, if the hypermetropia be of such a degree that for any given point of convergence it exceeds the positive part of the relative accommodation (Fig. 34, p. 50), one of two things must occur; either the patient must see indistinctly by not accommodating

sufficiently, or one eye must be allowed to converge. Some patients will prefer binocular indistinct vision; others, single clear vision with squint.

One occasionally finds an individual who can thus choose which he will do; we are trying his acuteness of vision at the distant type perhaps; he stops at some place, we will suppose $\frac{6}{12}$, and says that he is unable to read the next two lines unless he squint. The accommodation necessary to read $\frac{6}{6}$ makes a heavier call on the convergence than can be borne; such a case forms a good illustration of the manner in which convergent strabismus is produced in a hypermetrope.

Hence, if the impulse to see distinctly is greater than the desire to retain binocular vision, one eye yields, and squint occurs; at first diplopia follows the convergence, and is always in the opposite direction to the deviation. Possibly the convergence of the deviating eye is increased by the desire that the weaker image may be made still weaker, by falling on a more peripheral part of the retina. At first the diplopia may be very annoying, but by degrees the sensorium learns to suppress the image of the weaker eye, which after a time becomes amblyopic. The earlier the age at which the squint appears, the sooner does the sight in the deviating eye thus deteriorate.

Some observers deny that amblyopia is ever developed as a result of squint, but consider the amblyopia congenital, and therefore one of the combining causes of the strabismus.

There would, however, seem to be two distinct varieties of amblyopia met with in squint: in one the amblyopia is of a very high degree, the vision being reduced in some cases to mere hand reflex; this variety is incapable of improvement, and is probably congenital, or if not congenital it is the result of a want of development of the brain centres that preside over the vision of this eye.

The second variety of amblyopia is the result of want of practice, and consists of an awkwardness and difficulty in using the eye; frequently a patient will say that he is unable to see with the eye at all, and yet when encouraged to read with it and with the proper optical correction may succeed in reaching $\frac{6}{18}$ or even $\frac{6}{12}$; here practice is essential, in the hope that binocular vision may be regained.

In amblyopia it will often be found that the vision is best on the temporal part of the field, that part which is most used in peripheral vision.

In high degrees of hypermetropia, when no amount of accommodation can make vision distinct, squint is less likely to occur. It is usually, therefore, in cases of from 2 to 4 D. that convergent strabismus is most frequently met with, and it generally makes its appearance about the fourth or fifth year,—so soon, in fact, as the child begins to use its accommodation much for near objects.

Anxious parents frequently have all sorts of excellent reasons to which they attribute the defect; they say that the child has been imitating its playmate, or that the nurse did something which caused it to

squint, perhaps by making the child look too much, or too constantly in one direction.

Any cause which by rendering the image in one eye less distinct than that in the other, as nebulæ, ulcers of the cornea, a difference in the refraction of the two eyes, or even wearing a shade for a few days for some trivial complaint, may, where hypermetropia is present, combine to produce strabismus; the impulse for binocular vision is lessened, and the eye in which the fainter image is formed converges.

It is thus seen that convergent strabismus gradually destroys binocular vision. In cases of hypermetropia, where binocular vision does not exist owing to great difference in the refraction of the two eyes, divergent strabismus may occasionally occur.

This intimite connection between accommodation and convergence, together with the method of the production of strabismus, will be more easily understood by carrying out some such simple experiments as the following. We will assume the observer to be emmetropic: the strongest concave glass with which he, having binocular vision and being at a distance of six metres, can still read $\frac{6}{6}$, is the measure of the *relative* accommodation. The *absolute accommodation* is measured by the strongest concave glass with which each eye separately can read $\frac{6}{6}$. In my own case, with — 4 D. before each eye, $\frac{6}{6}$ can be seen singly and distinctly, — 4·5 D. renders it indistinct, and each increase in the glass increases the indistinctness, but produces no diplopia. Separately each eye can overcome — 7 D. Armed with — 4 D. before each eye,

I am able to see $\frac{6}{6}$ distinctly, using, of course, 4 D. of my accommodation; if a coloured glass be placed before one eye, homonymous diplopia at once appears, proving that one eye has deviated inwards; with − 3 D. and the coloured glass, squint was produced, but with no weaker concave glass.

On repeating the experiment in an individual with ·5 D. of myopic astigmatism in the right eye, and emmetropia in the left, − 2 D. before each eye was the strongest glass with which $\frac{6}{6}$ could be seen clearly and singly, − 2·5 D. did not render it indistinct, but produced diplopia. The absolute accommodation for each eye amounted to 6 D. With − 2 D. before each eye, the coloured glass was placed before the astigmatic one, and diplopia was produced. With − 1 D. and the coloured glass the result was the same, except that the two images were nearer together. With − ·5 D. actual diplopia was not produced.

These experiments require but little explanation. In my own case, when using 4 D. of accommodation, there is a tendency also to use a corresponding amount of convergence; I am conscious of this muscular disturbance by the effort I make, and by a feeling amounting almost to giddiness, produced when first looking through the − 4 D. The instintive desire to see clearly and singly is so great, that the external recti contract, thereby balancing the increased contraction of the internal recti. Any increase of my accommodation above 4 D. when looking at $\frac{6}{6}$ causes the letters to become indistinct,

the desire to maintain binocular vision being greater than that for clear images. On placing the coloured glass before one eye, we diminish the retinal impression in that eye; the demand for binocular vision is lessened, the external recti cease to act, and as a result of the increased action of the internal recti squint occurs.

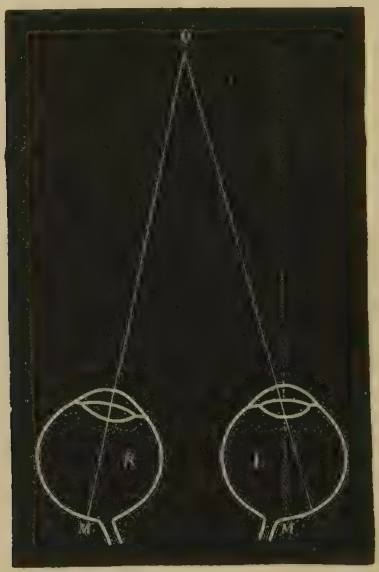
In the second experiment the retinal impression in one eye, even with so slight an amount of astigmatism, is reduced so that with 2 D. of accommodation the desire for clear images is greater than that for binocular vision, and diplopia, the symptom of squint, appears.

A certain number of cases of convergent strabismus get well with advancing age; this is most likely to take place when the vision in both eyes is good, though it sometimes occurs even where a high degree of amblyopia is present and binocular vision cannot exist. An unsatisfactory explanation sometimes given is, that as the accommodation diminishes, the time at length arrives when the amount of accommodation at the patient's disposal is not sufficient to produce clear images; he therefore relaxes his accommodation, and with it extreme convergence.

Divergent Concomitant Strabismus exists when one eye only fixes the object looked at, the other deviating outwards (Fig. 97); it is usually dependent on myopia, a state of refraction in which the convergence has to be used in excess of the accommodation if an image is to be formed on the macula of each eye; but divergent strabismus may occur in any eye in

which binocular vision does not exist, as in some cases of high hypermetropia or astigmatism; or it may result from a too free division of the internal rectus muscle, in attempting to cure a case of convergent strabismus. Divergent strabismus is also occasionally met with in emmetropia and hypermetropia, and is then due to congenital insufficiency of the convergence.

Fig. 97.



Divergent concomitant strabismus is much less common than the convergent variety.

In myopia the antero-posterior diameter of the

eyeball is elongated, the range of movement is diminished, and the extreme convergence which is necessary to enable the patient to see objects within his far point tires out the internal recti muscles, giving rise to muscular asthenopia: to relieve this one of the internal recti gives way, and the eye deviates outwards.

Sometimes the deviation only takes place after the patient has been working some time and the eyes feel fatigued; in others it is only noticed when looking at objects beyond their far point. Soon, however, the squint becomes constant, and a divergent strabismus once established usually increases.

In high myopia which is uncorrected by glasses, the patient has to hold objects so close to enable him to see them, that the necessary convergence becomes impossible, and binocular vision is therefore sacrificed.

The **treatment** of concomitant squint may be divided into three parts—

1. Optical.
2. Operative.
3. Educational.

The *optical treatment* consists in prescribing glasses which correct any error of refraction, and prevent excessive accommodation.

In concomitant convergent strabismus, when the squint has just commenced, and arises only under the influence of excessive accommodation necessary to enable the child to see near objects (periodic squint), then resting the eyes by allowing no near work to be

done, may suffice to remove the deviation, and so preserve binocular vision.

It is obvious that such treatment cannot be indefinitely carried out; therefore, it is essential that in all patients over three years of age the refractive condition of the eyes be accurately estimated under atropine, and the proper correcting glasses ordered for constant use, our object being to bring up the visual acuity of the patient to its highest standard.

When the convergent strabismus has already become permanent we must keep the patient under atropine for a week or two, correcting his hypermetropia with glasses at the same time, while he must be cautioned to abstain as much as possible from looking at near objects, the mere impulse of convergence being sufficient to produce the squint. In some cases this treatment will cure the strabismus; and if at the end of a year or so no recurrence of the squint has taken place, an attempt may be made to leave off the spectacles when out of doors, using them only for near work.

If the case belong to the less common variety of squint—divergent with myopia—we endeavour to give the patient as near as possible his full correction for constant use.

It will frequently be noticed that after the use of atropine the deviation may be diminished, or in slight cases it may have disappeared; this is due to accommodation being rendered impossible: these are the cases that are usually curable by glasses.

Should the child be too young for spectacles (under

three years), we must endeavour to prevent the increase of the squint, and also prevent the deviating eye from becoming amblyopic; this can best be done by keeping the child atropized for a few weeks at a time, and tying up the eye which does not squint for a short time each day, compelling the other to be used, and thus preserve its visual acuteness; this has, of course, no effect on the deviation, the covered eye converging under the bandage. After the age of three, spectacles may be prescribed.

Operative treatment.—In many cases, after the glasses have been worn for some months, the strabismus may still exist, and it may then be necessary to supplement the treatment by tenotomy. A free division of one muscle may cure a deviation of 15°: when a greater effect is required, both internal recti may be divided; or an advancement of one of the muscles may be necessary, with or without a tenotomy of its antagonist.

After the operation for convergent strabismus there should still remain a slight tendency to convergence when the glasses are removed; because as the child approaches the age of maturity the excessive innervation of the internal recti may subside, and then there may be danger of a deviation of one eye outwards.

Educative treatment.—In most cases it will be found that even when the deviation of the eye has been corrected, binocular vision is not obtained, and the cure of the case cannot be considered complete so long as binocular vision is absent; great patience

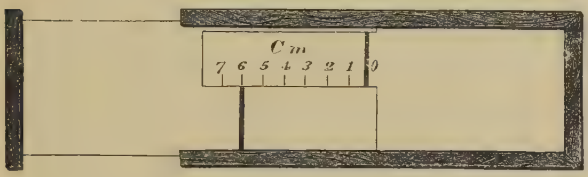
and care will be required in carrying out the necessary exercises.

Box stereoscopes are made for this purpose without prisms, but fitted with a clip at each sight-hole capable of taking the lenses of the ordinary trial box. The patient being emmetropic he will require in the clip a convex glass whose focal length corresponds with the length of the stereoscope; thus if it be 16 cm. long, he will require + 6 D.; should the patient be hypermetropic, 3 D.; then he will require + 9 D.; if myopic 3 D., then + 3 D. would be the glass required: the object is to enable him to see the slide at the end of the stereoscope without accommodating.

A convenient slide may be made, composed of two vertical lines, one above and the other below the same horizontal line, so arranged that the two lines can be made to recede or approach each other: this test object is placed in the box instead of the ordinary views. The two lines being now separated to a distance equal to that between the two eyes, and the clips containing the necessary convex glasses, the patient will see the lines without accommodation or convergence, and should succeed in fusing the two lines into one. When this is done binocular vision is obtained with parallelism of the lines of fixation. We endeavour at future trials to obtain fusion with an equal amount of convergence and accommodation. This is done by sliding the two lines towards each other about 1 cm.; this will call into play something like 1 m. a. of convergence; we then diminish the

convex glass 1 D., so that the amount of accommodation provoked (1 D.) may correspond to the amount of

FIG. 98 (Landolt).



convergence. In this way we slide the lines nearer and nearer together, diminishing the + glasses at the same time, until the two form one vertical line, then binocular vision is obtained with 6 m. a. of convergence and with 6 D. of accommodation; when this point has been reached, stereoscopic pictures may be used as slides.

When binocular vision does not exist, the patient should be taught to use the squinting eye, and this can be conveniently done by having a small, black, metal disc made to slip over the spectacle-glass of the fixing eye; with this eye excluded, the patient should read with the defective eye for fifteen minutes twice a day, commencing with large print where a high degree of amblyopia is present, and decreasing the size of the print gradually as the eye improves. In very young children the disc may be worn over the fixing eye for a part of each day, and the child encouraged to run about and play.

Another most useful exercise is the *reading bar*, which may be used for a short time twice a day

—a pencil, the finger, or a small strip of metal will answer the purpose; this is merely to be held about 6 or 7 cm. in front of the book when reading; if only one eye is used the patient stops when he comes to that part of the line covered by the bar; when both eyes are in use, then he goes on reading without any interruption.

Herring's drop test is perhaps the best test for finding out the presence of binocular vision.

Paralytic strabismus does not come within the province of this work.

See Case 22, page 255.

CHAPTER XI

ASTHENOPIA

Asthenopia (Ἀ, priv.; σθένος, strength; ὤψ, the eye), or weak sight, is a term used to designate a group of symptoms caused by fatigue or strain of some part of the eye or its muscles.

Asthenopia frequently accompanies hypermetropia, myopia, and astigmatism, and reference has often been made to it when speaking of these errors of refraction. It is also met with in cases where no ametropia exists, and may then be caused by over-fatigue or diminished power of the ciliary muscles, weakness of the internal recti, or exhaustion of an over-sensitive retina.

Asthenopia shows itself by the inability to sustain long and continuous near work, and is accompanied with more or less pain; the condition is a very common one, and it may be stated with confidence that pain in the eyes, unconnected with inflammation, is almost invariably due to asthenopia, and but seldom to any deep-seated disease. The more acute the pain, the more does it point to asthenopia; as a rule, however, the pain is not very severe: it may be situated in the eyes themselves, or around the orbits, and is always

increased when the eyes are used for near objects; in some cases no pain is felt, but after reading for a while the type becomes indistinct or double, so that the patient has to stop and look about the room, or rub his eyes, after which he may be able to resume reading for a short time, to be again quickly interrupted by a repetition of the same symptoms. If the work be still persisted in, the pain around the eyes increases, there is photophobia and lachrymation, a sensation of dazzling and dimness, more or less conjunctival congestion, the eyes becoming red and irritable; all these symptoms are liable to be worse in the evening after a day's work, when there is the additional disadvantage of an artificial light, which may be hot and irritating.

Headache is often a prominent symptom of asthenopia; it may take the form of heaviness or pain over the brow (which may or may not be combined with general headache); it is often periodic in character, and is always made worse by reading; frequently there is a tender spot on the top of the head, or pain in the occipital region, occasionally also there is pain in the back of the neck. These symptoms may be associated with dyspepsia, palpitation, and vomiting, and in some cases with obstinate insomnia.

This train of symptoms has occasionally been so severe as to lead to the diagnosis of brain disease, hence it is a good rule to test the refraction under atropine in all cases of persistent headache not giving way to ordinary medical treatment, and it must be remembered that a very slight amount of astigmatism

left uncorrected, even though the chief portion of it may be corrected, will be sufficient in some cases to keep up the headache.

There is little doubt that frequently reflex nervous disorders are caused by asthenopia.

Asthenopia may be divided into—

1. Accommodative.
2. Muscular.
3. Retinal.

Accommodative Asthenopia is exceedingly common, and is due to fatigue of the ciliary muscle; and may be met with in emmetropia or ametropia. It makes itself known by an inability to maintain the necessary accommodation, and may arise (*a*) from a weak condition of the ciliary muscle, (*b*) from excessive use, as in hypermetropia, (*c*) from unequal demand, as in astigmatism, (*d*) from unequal demand in the two eyes, as in anisometropia, (*e*) from diminished elasticity of the lens, as in presbyopia.

When Donders discovered the common occurrence of hypermetropia, he soon became aware of the intimate connection which existed between it and asthenopia, and was at first inclined to attribute every case to this cause. Where no manifest hypermetropia was present he gave a solution of atropine to paralyse the accommodation, feeling confident that some latent hypermetropia would then display itself; such cases were usually completely cured by proper convex glasses. This accommodative asthenopia is due in great measure to the constant and excessive action of the ciliary muscle, but partly also to the

abnormal relations existing between the two functions, accommodation and convergence; this statement is supported by the fact that hypermetropes who squint seldom suffer from asthenopia. An emmetrope looking at distant objects does so without any accommodation, the ciliary muscle being passive; but the hypermetrope has to use his ciliary muscle even for distant objects, and therefore much more for reading or near work; so that the ciliary muscle practically gets no rest. A young and vigorous person whose hypermetropia is not very high may resist asthenopia for a long time, but as he gets older, or if his health suffer from any cause, symptoms of this disorder are apt to appear, and when once established they may continue, notwithstanding improvement in the patient's general condition. In women asthenopia is very liable to come on during lactation.

Treatment.—We order such glasses as are necessary to correct the refraction according to the rules given. In some cases where convex glasses do not produce the desired relief, prisms of 2° bases inwards combined with the spherical correction are of great use, or in slight cases we place the convex glasses somewhat near together, so that the patient looks through the outer part of them (Fig. 101). This plan is frequently very useful in presbyopia. Here the asthenopia is due to a greater muscular effort being required to produce the necessary change in the shape of the less elastic lens, and perhaps, also, in part to the difficulty of maintaining an exact state of

equilibrium between the internal and external recti muscles.

In the hypermetrope there is a want of harmony between the accommodation and the convergence, the two functions having to be used in unequal degrees; and when we correct his refraction with glasses he will have to use these two functions equally, or at least in different proportions from that to which he has been accustomed. Many people are able at once to adapt themselves to this new state of affairs; but there are others in whom the force of habit is so strong that they cannot thus throw off the acquired one of using the accommodation in excess of the convergence. You must not, therefore, be discouraged if occasionally your patient is not at once and completely relieved of his asthenopia, as soon as you have given him convex spectacles. A fortnight's trial should be made before we can decide that such spectacles will not relieve the patient of his asthenopia.

Asthenopia depends much upon the nervous system of the individual; in some, a very slight amount of astigmatism will produce accommodative asthenopia; one hypermetrope will have no uncomfortable feelings, while another, whose condition seems exactly similar, will suffer much, so that it is essential to attend to the patient's general health.

Muscular Asthenopia is due to fatigue of some of the external muscles of the eyeballs.

The two eyes should be in a condition of perfect muscular equilibrium in every position of the eyes;

when this is not the case, it may be detected by covering one eye with a screen, while the other is made to fix a small object, such as the point of a pen, held about 30 cm. away; the covered eye should be accurately adjusted for the object, although it no longer sees it: when this is not the case the covered eye may deviate inwards or outwards; and if the screen now be withdrawn a movement of readjustment takes place.

Maddox has pointed out that in practice it will be found that on using the two functions of accommodation and convergence, the convergence has a tendency to lag behind the accommodation and requires the further stimulus of fusion to ensure the exact direction of the visual axes, so that when one eye is covered the other may deviate outwards a few degrees and still be considered within normal limits.

When this deviation of the covered eye is greater than 5°, then there is disturbance of the muscular equilibrium, and the condition is spoken of as *insufficiency* or latent convergence or divergence.

When insufficiency exists the results which follow vary.

1. Slight degrees may be corrected by increased innervation of the weak muscles, and so give rise to no symptoms.

2. Muscular asthenopia may result from excessive innervation; this may at once be relieved by closing one eye.

3. Or it may pass on to concomitant squint.

Heterophoria is the term now generally employed

to express a disturbance of the equilibrium of the muscles of the eyeball, and may be divided into—

1. Exophoria.
2. Esophoria.
3. Hyperphoria.
4. Insufficiency of the oblique muscles.
   - *a*. Hyperesophoria.
   - *β*. Hyperexophoria.

Exophoria, or latent divergence; one eye tends to turn out, and is only prevented from doing so by increased innervation of the internal recti muscles, there is, in fact, insufficiency of these muscles, resulting in a strain of the convergence.

Exophoria is the commonest of these defects, and is most frequently associated with myopia, though it occasionally occurs in emmetropia or even hypermetropia; it is characterised by inability to maintain prolonged convergence. The patient complains that the eyes become tired, especially during the evenings, reading or writing cannot be continued for any length of time; he has pain in and around the eyes, with headache; objects look dim and indistinct, and there is a tendency to see things double; sometimes the patient experiences a sensation as if one eye had turned outwards, which may really be the case; frequently the patient finds relief by closing one eye.

In myopia the disturbance of the two functions accommodation and convergence, may in some measure tend to the production of this form of asthenopia. Thus a patient with 4 D. of myopia has his punctum

remotum at 25 c.m. ; to see an object at that distance he must converge to that point, maintaining at the same time a passive condition of his accommodation.

Strain of the internal recti muscles is essentially dependent upon binocular vision ; no convergent strain can exist where binocular vision is not present.

Esophoria, or latent convergence, is due to insufficiency of the external recti, and is seldom seen, for it quickly passes on to convergent squint with loss of binocular vision ; here, as a rule, we are dealing with excessive innervation of the internal recti muscles rather than with an insufficiency of their opponents.

Hyperphoria, one eye tends to deviate upwards ; this is usually associated with esophoria, but may exist alone ; this is not a very uncommon defect.

Insufficiency of the obliques I have never seen, and no cases have been recorded in this country, though they seem to occur in America.

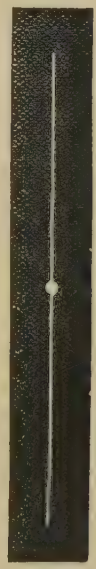
To test and record the amount of latent deviation, the glass-rod test described on page 46, may be employed. The patient is directed to look at the flame of a candle 6 metres away ; immediately behind the flame is a scale for measuring the amount of deviation ; the glass rod is then placed horizontally before the right eye in testing for exophoria or esophoria : if the streak of light appear on the right of the candle homonymous diplopia is present, and the condition of the eyes is one of convergence : whereas if the streak has its position on the left side of the candle, crossed diplopia is present, and the eyes are divergent ; the number on the scale corresponding

with the position of the streak of light indicates the amount of convergence or divergence. When employed for hyperphoria the rod must be placed before the eye vertically.

Another test for detecting insufficiency of the convergence is sometimes employed.

Place a prism of about 15°, with its base downwards, in a spectacle frame before one eye: by this means we cause a displacement of the eye upwards which produces vertical diplopia. The patient is now directed to look steadily at a card, on which is drawn a line with a dot in its centre, placed at the patient's ordinary reading distance (Fig. 99). Naturally he will see two dots. If he see one line only with two dots on it, his muscles are assumed to be of the normal strength; if, however, two lines are seen with a dot on each, then insufficiency exists, and the strength of the prism which is necessary with its base inwards to produce fusion is the measure of the insufficiency.

Fig. 99.

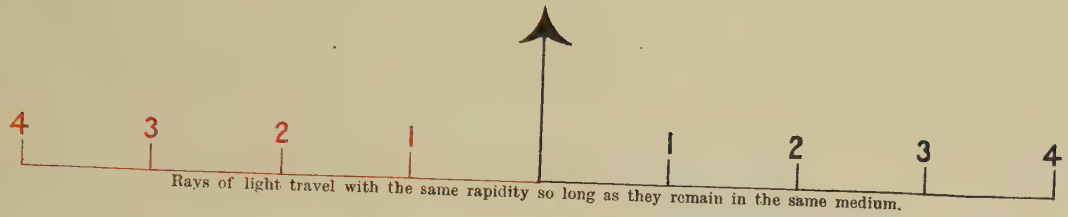


The most satisfactory test for muscular insufficiency is, however, the *rod test*; and having recorded the amount of *latent convergence* or *divergence* for distance, we next ascertain if there is any latent deviation in near vision.

A prism of 12° base upwards being placed before the right eye in a spectacle frame, the scale is held $\frac{1}{4}$ metre from the eyes. The scale used by Maddox

consists of a horizontal line in the centre of which is an arrow pointing upwards (Fig. 100). The line is divided into metre angles which are marked by figures, black on the right of the arrow, red on the left. The prism of course causes two arrows and two lines to be seen: the patient is directed to fix the fine print just below the arrow, and if there is no deviation the two arrows will be seen, one immediately below the other; if the lower one point to the right (black figures) there is latent convergence, but if to the left (red figures) latent divergence for this distance: the amount of deviation is read off the scale and duly recorded.

Treatment.—In cases of myopia we give such glasses as correct the refraction to be worn constantly; these frequently succeed in relieving the asthenopia. When this is not the case, weak prisms bases inwards, by which we diminish the amount of convergence necessary, often give instant relief. It is sometimes useful to combine the prisms with concave glasses, or by separating the glasses somewhat widely we may produce the same result. Fig. 101 shows concave spectacles, which act as prisms by being slightly separated; convex glasses have the same effect when placed so close together that the patient looks through the outer part of the lenses. Or the lenses, instead of being thus displaced, may be *decentred* by so grinding the glass that its optical centre is not the centre of the glass. These decentred glasses are spoken of as *prismospheres*, and when ordered the amount of decentration should be



Rays of light travel with the same rapidity so long as they remain in the same medium.

Bale & Danielsson, Ltd. lith.

stated in millimetres on the order card; the more the glasses are decentred the greater will be the prismatic effect produced (page 194).

When actual divergence of one eye takes place, advancement of the internal rectus, with or without division of its antagonist, may be necessary.

Fig. 101.

Retinal Asthenopia is due to fatigue of the retina.

In addition to those cases of asthenopia occurring with hypermetropia, myopia, and astigmatism, which should be relieved by the proper optical correction

restoring the balance of the extra- and intra-ocular muscular systems, every one will occasionally meet with cases where there is intense discomfort and inability to read or do near work for any length of time, but where no ametropia exists, as proved by placing the patient under atropine and then testing the refraction. The visual acuteness is often very good, frequently rising to $\frac{6}{5}$ or higher. The pain complained of is usually at the back of the eyes, with more or less headache, photophobia, lachrymation, a feeling of tension and heat, together with itching and pricking of the eyelids. Sometimes the chief symptom complained of is the conjunctival irritation accompanied with increased secretion.

These cases are always exceedingly troublesome and difficult to cure; they occur most frequently among young unmarried girls of an hysterical or nervous temperament. Less frequently men are affected, and then it is chiefly amongst those who are feeble, hypochondriacal, and nervous.

With the ophthalmoscope the eyes may appear quite normal, or the retinal veins may be full with or without some slight haziness of the edges of the discs; the perimeter may reveal a spiral contraction of the visual fields due to progressive exhaustion of the retina, which probably follows reflex contraction of the retinal vessels.

Retinal asthenopia may be attributed to long hours of near work which has been done by artificial light, especially in those who have been previously reduced by some lowering illness. I have met with several

cases amongst those making gold lace, and no doubt the bright materials here worked with had something to do with the production of the retinal hyperæsthesia.

It seems generally accepted by all authorities on this subject that in most cases the nervous system is exceedingly sensitive and unstable.

Sometimes the asthenopia is distinctly of reflex origin, produced by disturbance of the internal organs; when leucorrhœa exists in young unmarried women, with troublesome asthenopia, masturbation may be suspected. Irritation of the fifth nerve from carious teeth may also act as the exciting cause.

Treatment.—Complete abstinence from near work does not always give relief, nor is this abstinence to be encouraged. A slight amount of regular work should be done every day, with rest for the eyes during the evening. Usually some form of nerve tonic is indicated, with plenty of outdoor exercise and the avoidance of strong light or places where there is a great glare, such as the sea-side in summer. Tinted glasses are to be avoided, since they merely tend to increase the hyperæsthesia of the retina.

CHAPTER XII

SPECTACLES

Having referred to the subject of spectacles when considering the correction of the different forms of ametropia, I will now briefly recapitulate what was then said, even at the risk of being accused of unnecessary repetition.

Hypermetropia.—So long as $\frac{6}{6}$ can be read with each eye, no glass is necessary for distant vision; for reading and near work we give such glasses as correct the *manifest* and $\frac{1}{5}$ of the *latent* hypermetropia.

If distant vision be improved by convex glasses, then these may be prescribed.

In hypermetropia complicated with strabismus we estimate the total hypermetropia under atropine, then give the full correction to be worn constantly.

Myopia.—In cases of low degree we may prescribe folders for distance, and allow the patient to read and write without glasses if only he keep a sufficient distance (30 cm.) from his book and suffer no inconvenience. In medium degrees the best results often ensue when the full correction is worn constantly both for near and distant objects.

Where the myopia is of high degree the full correction may be satisfactory for distance, but uncomfortable or impossible for reading, owing to the accommodation being insufficient. These glasses also have the disadvantage of diminishing the size of objects; here we give two pairs of spectacles, one for distance, and a weaker pair for reading.

Astigmatism.—Our object is to give as near as possible the full correction (found by atropizing the patient); these glasses should be worn constantly.

Atropine is seldom necessary in patients over twenty years of age. Homatropine and cocaine is usually sufficient in older people.

Convex glasses render parallel rays which pass through them convergent; they add therefore to the refraction of the dioptric system, and are called *positive.*

Concave glasses render parallel rays divergent; they therefore diminish the refraction of the dioptric system, and are called *negative.*

Convex glasses add to the quantity of light entering the eye, while concave glasses diminish it.

The size of the image is modified: thus positive glasses bring forward the nodal point, and so increase the size of the image; while negative glasses carry the nodal point backwards, and so diminish the size of the image.

Glasses may be made of rock crystal (commonly called pebbles) or crown glass. Those made from the former material have the advantage of being harder, and are therefore less likely to be scratched than

glass; the weight is much the same in both cases. Pebbles absorb more heat, and unless cut exactly at right angles to their optic axis they are apt to refract unequally; besides, it is difficult to get rock crystal free from striæ, so that lenses made from good crown glass are quite equal to the best pebbles, very much cheaper, and almost universally used.

The method of mounting spectacle glasses is of the greatest importance; they must be accurately centred in frames that are light, strong, and fit comfortably, otherwise the good effect of the most carefully chosen correction may be entirely frustrated by a faulty position of the glasses, or even a fresh source of eye-strain may be introduced. Glasses for constant use should be in the same plane and centred for distance; those intended for near work only should converge slightly, and be centred for the reading distance.

Each lens should be in the first focal plane of the eye, that is 13·7 mm. in front of the cornea. When this is the case, the images formed on the retina will be of the same size as in emmetropia.

The bridge of the frame should be moulded to suit the shape of the nose, resting on it by a broadish surface so as not to cut or indent the skin, while the glasses should be a sufficient distance from the eyes to just clear the lashes. The sides of the frames should pass back immediately above the ears, and in many cases, especially where glasses are required to be worn constantly, they may with advantage bend directly round the ears, fitting the posterior part of the concha; these ear-pieces may be made of twisted

wire, which gives them considerable elasticity and strength. The frames may be made of gold or steel; the latter material has the disadvantage of rusting easily.

When glasses are worn for myopia or hypermetropia they should not be further from the eye than 13·7 mm. For presbyopia the person may be allowed to suit his own convenience and comfort, 2½ cm. being an ordinary distance.

Single glasses may occasionally be allowed in low degrees of myopia for looking at distant objects. They have the disadvantage of encouraging monocular vision, and sometimes one eye is used so entirely that the sight in the other may deteriorate from want of sufficient use.

Folders (pince-nez), of which there are many varieties, may be used in some cases of hypermetropia and myopia; many presbyopes find them very convenient for reading. Spectacles are as a rule to be preferred, especially in children, since they are more accurately centred and fit better.

In cases of astigmatism it has hitherto been the custom to order spectacles and not folders, as in the latter it is difficult to be certain that the cylindrical glasses are always in their proper axis; but lately several ingenious pince-nez have been brought out which are free from this objection. That form in which the glasses slide on a horizontal bar are so arranged that they fit on the nose very easily, and are extremely comfortable, and may be recommended in many cases.

In addition to concave, convex, and cylindrical glasses, others are sometimes used.

Stenopaic spectacles consist of an opaque screen with a small central aperture which may be of any shape to suit a particular case, so that all the peripheral rays are cut off, only those that are in the visual axis being allowed to pass through. They can be combined with convex or concave glasses, and are sometimes exceedingly useful in cases of leucomata, nebulæ, irregular astigmatism, conical cornea, etc., where the vision is much disturbed.

Prismatic spectacles may consist of prisms alone, or they may be in combination with concave or convex lenses. It is not convenient to use prisms much stronger than 3° or 4°, owing to their weight. They are useful in certain cases of paralysis of muscles, to correct the diplopia, and in some cases of hypermetropia, myopia, and astigmatism which are not relieved by their proper correction; prisms are also used for testing the ocular muscles and for detecting malingerers. When ordered in cases of asthenopia with errors of refraction, they may be combined with the glasses which correct these errors (p. 194).

Pantoscopic Glasses.—The upper half of these glasses have one focus, the lower half another. Thus a presbyopic person may also be myopic. The upper half of the glass would then be concave for distance, the lower half convex for near work. Painters sometimes find such glasses very useful.

Tinted glasses are often required for diminishing excessive light, especially where there is irritation

or inflammation of the retina; they are also useful in some cases of photophobia, arising from various causes, as myopia, etc. Where the aim is to relieve the retina without injuring the distinctness of vision the light blue glasses are the best, as they cut off the orange rays; where the object is to act on the quantity and not the quality of the light, smoke-coloured glasses are to be preferred. Tinted glasses sometimes do real harm, as in cases of asthenopia, by increasing the sensitiveness of the retina; they are always somewhat heating to the eyes, in proportion to the amount of rays they absorb. We sometimes combine them with convex or concave glasses.

There are also various forms of *protectors*; those hollowed out like a watch-glass, so as to fit closely, are to be preferred to those with wire sides called goggles, or those with sides of glass, which have the disadvantage of being too heavy. Workmen wear different sorts of protectors to keep off dust, fragments of stone, etc., which may be made of glass, talc, or other material.

Shot-proof spectacles are also made for sportsmen.

It is sometimes necessary to find out and record the strength of glasses that are being worn; this is easily done. If convex, we take a concave glass out of the trial box, hold it against the glass we are trying, and look through them at a line, *e. g.* the bar of a window or any similar object. We move the glasses to and fro in front of the eye: if the line remain immoveable the neutralisation is complete;

if it move in the same direction the concave glass is too strong; if in the opposite direction it is not strong enough.

A small lens measure is now made for estimating the strength of lenses.

Cases

Commence the examination in a systematic manner. First, notice the general appearance of the patient, then the shape of the head and face. Next the eyes, as to whether they are large and prominent, or small and sunken-looking. Listen patiently to the sufferer's complaints, and having submitted to this ordeal, test the acuteness of vision of each eye separately, and afterwards together, writing down the result, remembering always to commence with convex glasses. Then place the near type in the patient's hand, noting the number of the type and the distance at which it can be read. Next pass on to the ophthalmoscope, first applying the "retinoscopic test," then the "indirect examination," and finally the "direct method," first at a distance, and then close to the eye. If any ametropia exist, the advisability of paralysing the accommodation with atropine must be considered.

In order to illustrate this method of examination, I will give a few cases in addition to those which will be found at the end of the chapter on Retinoscopy.

Case 10. *Hypermetropia.*—E. M—, a young woman,

a book-folder, æt. 17, suffering from tinea tarsi, complains that her eyes get very tired at night, so much so, in fact, that she is unable to read for any length of time. Her general appearance is healthy, and nothing special is noticed about her face, except that the eyes are small. The acuteness of vision for both eyes is normal. On placing + 1 D. in front of the right eye, $\frac{6}{6}$ is seen more distinctly than without, with + 2 D. $\frac{6}{6}$ is still read, with + 2·5 D. vision is not so good; the same result is obtained with the left eye. + 2 D. for each eye is the strongest convex glass with which $\frac{6}{6}$ can be read, and is therefore the measure of her Hm.; on trying the two eyes together + 2·5 D. still gives $\frac{6}{6}$. We record it thus:

$$\left.\begin{array}{l}\text{R.V. } \frac{6}{6} \text{ Hm. 2 D.} = \frac{6}{6} \\ \text{L.V. } \frac{6}{6} \text{ Hm. 2 D.} = \frac{6}{6}\end{array}\right\} \text{Hm. 2·5 D.} = \frac{6}{6}.$$

On placing the patient in the dark room, and directing her to look at some distant object or at a black wall, so as to relax as much as possible the accommodation, with the concave mirror the shadow we perceive moves slowly against the mirror. We put + 2 D. in a spectacle frame, in front of the eye; the shadow is more distinct, and moves more quickly. We try stronger glasses, and then find that + 3·5 D. is the highest with which we still get a reverse shadow. Both eyes are alike.

Next examine with the ophthalmoscope. By the indirect method the disc becomes smaller on withdrawing the objective from the eye. With the mirror alone at a distance, we see an image of the

disc which moves with the observer's head, proving the image to be an erect one. On approaching the eye the disc is not seen well, unless we put in force our own accommodation. With our accommodation suspended, we turn the wheel of the ophthalmoscope so as to bring forward convex glasses; the clearness of the fundus is improved; + 4 D. is the strongest convex glass with which the details can be distinctly and clearly seen by myself.

We might be satisfied with this result, assuming 4 D. to be the amount of total hypermetropia, but in young people it is much more satisfactory to be able to record once and for all the total hypermetropia beyond doubt. Atropine (grs. iv to ʒj) was therefore ordered, one or two drops to be placed in both eyes three times a day for four days, warning her that she will be unable to see well, and that the pupils will be dilated during their use. We also recommend a shade to be worn to protect the eyes from the light.

On her return she reads only $\frac{6}{60}$ with each eye, and she now requires + 5 D. to enable her to read $\frac{6}{6}$. We also find with retinoscopy that + 5 D. is the strongest glass with which we get an opposite shadow.

Our patient, therefore, has a total hypermetropia of 5 D., two dioptres of which were manifest, and three latent. For work and reading we order her spectacles + 3 D. At present she will not require them for distance. About thirty she will probably require her glasses increased to + 4 D.; about forty

she may be able to bear her full correction, and may then begin to wear them constantly.

We must remember that when atropine has been used it is necessary to take off 1 D. from the measurements thus found.

Case 11. *Myopia.*—A young man, æt. 20, next presents himself. He has a long intellectual face with prominent nose; the palpebral apertures are wide; and on directing him to look inwards as much as possible, the eyeballs seem elongated in the antero-posterior diameter.

His eyes, he says, are excellent, but he is unable to recognise people as well as formerly. We test the acuteness of vision, and find that he reads $\frac{6}{36}$ with each eye. Convex glasses make even that line indistinct. Our patient is probably myopic. We place in his hand the near type, and he reads No. 1 at once and easily. The farthest point at which he can read it is 25 cm. ($\frac{100}{25}$ = 4 D.); − 4 D. should be the measure of his myopia. We try − 4 D., directing him again to look at the distant type. He reads with each eye $\frac{6}{6}$; we reduce the glass to find the *weakest* with which he reads the same, and with − 3·5 D. he reads it, though hardly so well; with − 3 D. he reads only $\frac{6}{9}$; − 3·5 D. is therefore the measure of his myopia, and we record it thus:

R.V. $\frac{6}{36}$ − 3·5 D. = $\frac{6}{6}$.
L.V. $\frac{6}{36}$ − 3·5 D. = $\frac{6}{6}$.

If we employ retinoscopy − 3·5 D. is the weakest concave glass with which a reverse shadow is produced.

We next subject the eye to the indirect ophthalmoscopic examination. The image of the disc becomes larger on placing the objective near the eye and gradually withdrawing it, and in addition we see also a slight myopic crescent on the apparent inner side of the disc. From this case, disc No. 1 was drawn (p. 147).

With the mirror alone at a distance from the eye the disc cannot be well seen, because in our case the aërial image will be formed about 25 cm. in front of the patient's eye. To enable us to see this aërial image it is necessary we should be some 30 cm. away from it; so that we should require to be 25 + 30 = 55 cm. from the observed eye, and at that distance the illumination will be very weak.

With the direct method the details appear blurred until we put on a concave glass by turning the wheel of our refracting ophthalmoscope. The weakest concave glass with which we are able to see the details of the fundus clearly is the measure of the myopia. Thus we have four distinct plans of measuring our case of myopia:

1st. The farthest distance at which the near type is read, 25 cm. ($\frac{100}{25} = 4$ D.).

2nd. The *weakest* concave glass which gives the greatest acuteness of vision.

3rd. The *weakest* concave glass with which we get a retinoscopic shadow moving in the opposite direction to the movement of the concave mirror.

4th. The *weakest* concave glass with which the

details of the fundus can be distinctly seen by the direct method.

Should any of these results vary much, we should suspect that the myopia is increased by spasm of the accommodation, and we atropize the patient in the manner before described, and at the end of four days go over the ground again, remembering that when atropine has been used, it is necessary to add on about − ·5 D. to the glass found, because the ciliary muscle is probably never so completely relaxed as when it is under the influence of atropine.

Having found, then, that our patient's myopia amounts to − 3·5 D., we give spectacles of that focus for constant use. In addition to ordering spectacles, we give him also some very important general directions: he must always hold his book or work 35 cm. away, bring the work to his eyes, and not his eyes to the work; writing should be done at a sloping desk, he should sit with his back to the window, so that the light comes over his left shoulder on to his work, and do as little near work as possible by artificial light.

Case 12. *Hypermetropia and Presbyopia.*—A gentleman, æt. 56, comes with the complaint that he cannot see to read as comfortably as formerly, though he sees distant objects well. We try his acuteness of vision, and find that he reads $\frac{6}{9}$ badly. With + 1 D. he sees much better, reading some of the letters of $\frac{6}{6}$. We then try + 1·5 D., and these he rejects. Hence we conclude that he has Hm. 1 D. We know from his age that he will also be presbyopic 3 D., and we add

on to this + 1 D. for his hypermetropia, directing him to read the newspaper with + 4 D. for half an hour. He thinks these rather strong for him, as they make his eyes ache. With + 3·5 D. he feels quite comfortable, and we therefore give him + 3·5 D., telling him that he may require them changed for slightly stronger ones in about five years.

Case 13. *Paralysis of the Accommodation.*—Kate L—, æt. 12, has been very ill from diphtheria, but is now much better. She complains that she is unable to read or work, though able to see distant objects well. The pupils are very large, and act badly to light. Hence we suspect paralysis of the accommodation. We test her acuteness of vision, and she sees $\frac{6}{6}$ with each eye. We try convex glasses ·5 D., and she still reads $\frac{6}{6}$, but 1 D. she rejects. Our diagnosis is therefore confirmed. We next find the weakest glass with which she is able to read, *weakest* because we are anxious to encourage the ciliary muscle to act, since by replacing it entirely we should prolong the patient's recovery.

The glasses must be changed for weaker ones as the ciliary muscle recovers tone.

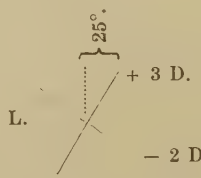
We saw that she had a slight amount of hypermetropia, and also that there was some accommodation left, enough at least to correct this, otherwise she could not have read $\frac{6}{6}$ without + ·5. A tonic containing iron and strychnine was also prescribed.

Case 14. *Anisometropia.*—A young woman, æt. 20, has never seen well, either at a distance or near at hand; has tried spectacles of all sorts, but never been

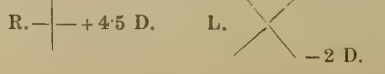
able to find any that suited her. The eyes look somewhat irritable, but there is nothing conspicuous about their size or shape. There is some want of symmetry about the face, the nose being deviated from the median line slightly to the left.

We first try the acuteness of vision of the right eye. She reads $\frac{6}{12}$, and with + 1 D. vision is somewhat improved; with + 1·5 D. it is made worse. Still armed with + 1 D. we direct the patient to look at the fan of radiating lines (Fig. 85). She sees plainly the horizontal lines, whilst all the others are more or less indistinct, the vertical line most so; still looking at the horizontal line, we alternately hold in front of + 1 D., which is before the eye under examination, + ·25 D., which makes it worse, then − ·25 D., which she says at once makes it perfectly clear and distinct. We therefore put down + ·75 as the correction for the vertical meridian, and pass on to the horizontal. Our patient is directed to look steadily at the vertical line. We try convex glasses, these improve it, + 3 D. making it quite clear; a stronger glass than this renders it slightly indistinct. It is evident, therefore, that her horizontal meridian is hypermetropic + 3 D. We put up the correction found, + ·75 D. sp., + 2·25 D. cylinder axis vertical, and direct her again to look at the distant type; $\frac{6}{6}$ is read, though with some difficulty. This result is not, however, reliable, and we proceed to confirm it by retinoscopy, obtaining + 2 D. for the vertical, and + 4 D. for the horizontal meridians. On trying this correction, however, the vision is not so good. We now test the

acuteness of vision in the left eye; she sees $\frac{6}{36}$, and neither convex nor concave glasses improve it. On looking at the fan of radiating lines, all seem indistinct, and having thus far no data to go upon, we, instead of wasting time, at once pass on to retinoscopy. We get oblique shadows, the horizontal moving with the mirror, and the vertical against it; here, then, is a case of mixed astigmatism. We find out that — 2 D. is the weakest concave glass with which we get a reverse shadow horizontally, and + 3 D. the strongest convex lens with which an opposite shadow is still obtained in the vertical meridian, the degree of obliquity being about 25°. This result is noted down thus:



We therefore place in a spectacle frame + 3 D. spherical, combined with — 5 D. cylind., axis deviating outwards from the vertical 25°. With this correction the patient at once reads $\frac{6}{12}$. We are not to be satisfied with this result, but give the patient a solution of sulphate of atropine, grs. iv to ℥j, with directions to come again in four days. At the end of that time she returns, and we find with retinoscopy—



The right eye with this correction reads $\frac{6}{6}$ readily, and the left also $\frac{6}{6}$, but rather slowly. This result is very satisfactory. We now allow the patient to recover from atropine, and at the end of a week confirm the result before ordering spectacles. Then for the right eye the best vision was obtained with + 1·5 sp. ⌓ + 2 D. cy. axis vertical ($\frac{6}{6}$); and for the left + 3 D. spherical ⌓ − 5 D. cylind. axis 20° from the vertical ($\frac{6}{9}$). These spectacles were therefore ordered, and the patient directed to wear them constantly.

Case 15. *Anisometropia.*—Jane W—, æt. 30, presents herself, complaining that the sight in her left eye has been gradually getting dim for some months. She is a small, healthy-looking woman, with nothing characteristic in her appearance. We test the acuteness of vision:

Right $\frac{6}{6}$ Hm. 1 D. = $\frac{6}{6}$.

Left $\frac{6}{18}$, not improved with spherical glasses.

We try retinoscopy, but the pupils are so small that the result is not very satisfactory. We are, however, able to make out in the left eye a reverse shadow in the horizontal meridian, which + 2 D. over-corrects, + 1·5 D. being the highest glass with which we get an opposite shadow; the vertical meridian appears emmetropic. There is, therefore, no doubt that the defective vision in this eye is due to astigmatism. The patient complains that the examination has made her eyes ache, so we do not proceed further, but order a solution of hydrobromate of homatropine (2 grs. to the ℥j) to be used every three hours,

and direct her to come again on the following day. Then the result with retinoscopy is—

R. + 1·5 D.
+ ·5 D.
L. + 2 D.

We try this at the test type.

R. $\frac{6}{24}$ + 1·5 D. = $\frac{6}{6}$.
L. $\frac{6}{36}$ c̄ $\frac{+ \cdot 5 \text{ D. sp.}}{+ 1{\cdot}5 \text{ D. cy. axis vert.}}$ = $\frac{6}{6}$.

We make a slight deduction from the sphere in each case for the homatropine, and order for constant use—

R. + 1 D. sph.
L. + 1·5 D. cy. axis vert.

Case 16. *Presbyopia.*—John G—, æt. 50, has always enjoyed good sight; he still sees distant objects well, but finds some difficulty in reading, especially during the evenings.

R.V. $\frac{6}{6}$, no Hm.
L.V. $\frac{6}{6}$, no Hm.

We try him with + 2 D. for reading, and with these he sees perfectly; this, therefore, is a simple case of presbyopia, requiring a pair of folders + 2 D. for reading, writing, etc.

Case 17. *Hypermetropia and Presbyopia.*—Mr. K—, æt. 60, sees badly both near and distant objects; he wears + 4 D. for reading, but they are not comfortable.

R.V. $\frac{6}{36}$ Hm. 3 D. = $\frac{6}{9}$.
L.V. $\frac{6}{36}$ Hm. 3 D. = $\frac{6}{9}$.

He therefore wants + 3 D. for distance; and to find the glass he will require for reading, it is necessary to add on to this distance lens the glass he would require for presbyopia if he were an emmetrope, viz. + 4 D. We therefore try him with + 7 D., but these make his eyes ache; we next try + 6·5 D., and with these he sees comfortably.

This patient, then, requires two pairs of spectacles,—

+ 3 D. for distance;
+ 6·5 D. for reading, &c.

Case 18. *Myopia and Presbyopia.*—Mrs. C—, æt. 55, complains that her eyes become tired at night; she has tried several pairs of spectacles, but without finding any that exactly suit her.

R.V. $\frac{6}{36} - 2$ D. $= \frac{6}{9}$.
L.V. $\frac{6}{36} - 2$ D. $= \frac{6}{9}$.

Our patient requires, therefore, this correction for distance, but she also wants spectacles for reading and near work; an emmetrope of fifty-five requires presbyopic glasses + 3 D.; she is, however, a myope of 2 D., so we have to deduct this from the presbyopic glass ((+ 3 D.) + (− 2 D.) = + 1 D.), and try the + 1 D. for reading. With these she is able to read the smallest type comfortably; we therefore prescribe two pairs of spectacles,—

− 2 D. for distance;
+ 1 D. for reading.

Case 19. *Myopia.*—Annie C—, æt. 9, was brought because she was unable to see the black-board at school.

R.V. $\frac{6}{24} - 3{\cdot}5$ D. $= \frac{6}{9}$.
L.V. $\frac{6}{24} - 2{\cdot}5$ D. $= \frac{6}{9}$.

After using atropine—

R.V. $\frac{6}{36} - 3$ D. $= \frac{6}{9}$.
L.V. $\frac{6}{24} - 2$ D. $= \frac{6}{9}$.

Ordered spectacles for distance R. — 3 D., L. — 2 D., with directions to present herself again in six months, when, should the myopia have increased, or should the child complain of asthenopia, it may be necessary to prescribe spectacles for constant use.

Case 20. *Simple Myopic Astigmatism.*—Thomas J—, æt. 20, sees rather badly both near and distant objects.

R.V. $\frac{6}{12}$, not improved with spheres; with pin-hole $= \frac{6}{9}$.
L.V. $\frac{6}{12}$, not improved with spheres; with pin-hole $= \frac{6}{9}$.

After atropine had been used for four days retinoscopy gave—

R. +1 D. cy. axis horiz. $= \frac{6}{6}$.
L. +1 D. cy. axis horiz. $= \frac{6}{6}$.

After the atropine has passed off—

R. −1 D. cy. axis vert. $= \frac{6}{6}$.
L. −1 D. cy. axis vert. $= \frac{6}{6}$.

This correction was given for constant use.

Case 21. *Compound Myopic Astigmatism.*—Miss M—, æt. 13, has seemed short-sighted for the last year or two. Mother and father both have good sight.

R.V. $\frac{3}{60} - 9$ D. $= \frac{6}{24}$.
L.V. $\frac{3}{60} - 9$ D. $= \frac{6}{24}$.

The pupils are large, so that retinoscopy can be easily carried out.

R.— −10 D. / −−6 D. L.— −10 D. / −−7 D.

R.V. $\bar{c}$ $\frac{-6 \text{ D. sp.}}{-4 \text{ D. cy. axis horiz.}}$ $= \frac{6}{18}$ and 2 letters of $\frac{6}{12}$.

L.V. $\bar{c}$ $\frac{-7 \text{ D. sp.}}{-3 \text{ D. cy. axis horiz.}}$ $= \frac{6}{12}$.

On examination of the eyes with the ophthalmoscope the choroid is found to be exceedingly thin, there is a large crescent in both eyes, and in the right are three or four patches of choroiditis, with one hæmorrhage near the macula.

The patient was ordered the full correction for distance, and advised to do no reading, writing, or near work for six months, then to return for inspection; she was also recommended to spend as much of her time as possible in the open air, and a mixture containing syrup of the iodide of iron was prescribed.

Case 22. *Concomitant Squint.*—George W—, æt. 5, has squinted inwards for the last three months. On covering the non-squinting eye and directing the little boy to look at the finger held a short distance from him, the deviating eye immediately righted itself and fixed the finger, the covered eye at the same time turning in. We prescribed a solution of sulphate of atropine to be applied to both eyes, and at the end of a week the patient is brought back: the squint is now much less apparent, and with retino-

scopy we find 3·5 D. of hypermetropia in each eye. The direct examination gives the same result. We order our patient spectacles + 2·5 D. to be worn constantly.

Case 23. *Aphakia.*—Thomas B—, æt. 50, gamekeeper. Had the right lens removed for cataract nine months ago, and last week the opaque capsule remaining was needled.

R.V. $\bar{c}$ + 11 D. = $\frac{6}{9}$, and with + 14 D. No. 1 of the near type was read with comfort; the patient was therefore ordered the following spectacles:

+ 11 D. for distance;
+ 14 D. for near work.

These were arranged in a reversible frame, so that either glass could be brought in front of the right eye as occasion required.

APPENDIX

In the metrical system the unit of length is a metre, equal to 100 centimetres, 1000 millimetres, or 40 English inches; so that 1 inch is equal to $2\frac{1}{2}$ centimetres. A lens of 1 metre focus is called a dioptre, a lens of $\frac{1}{2}$ a metre (50 cm.) is 2 D., $\frac{1}{10}$ of a metre (10 cm.), 10 D., etc.

In the old system the lenses were numbered according to their focal length in inches, a lens of 1-inch focus being the unit; a lens of 2-inch focus was expressed by the fraction $\frac{1}{2}$, one of 10-inch focus $\frac{1}{10}$, and so on. If we wish to convert a dioptric measurement into the corresponding inch measurement of the old system, we have only to remember that the unit 1 metre = 40 English inches, so that a glass of 1 D. = $\frac{1}{40}$ in the old system, 2 D. = $\frac{2}{40} = \frac{1}{20}$, 5 D. = $\frac{5}{40} = \frac{1}{8}$, and so on.

The table on the next page gives approximately the equivalent of each dioptre or part of a dioptre in English and French inches, and their focal length in centimetres.

Dioptres.	English inches.	French inches.	Centimetres.

Regulations for Candidates for Commissions in the Army

A candidate must be able to read at least $\frac{6}{36}$ with each eye separately without glasses, and this must be capable of correction with glasses up to $\frac{6}{6}$ in one eye and $\frac{6}{12}$ in the other; he must also be able to read No. 1 of the near type with each eye without the aid of glasses.

Squint, colour-blindness, or any serious disease of the eye renders the candidate ineligible.

Navy

A candidate must be able to read $\frac{6}{6}$ with each eye, and the near type at the distance for which it is marked, without glasses.

Colour-blindness, squint, or any disease of the eye disqualifies.

Indian Civil Service

A candidate must be able to read $\frac{6}{9}$ with one eye and $\frac{6}{6}$ with the other, with or without correcting lenses.

Any disease of the fundus renders the candidate ineligible. Myopia, however, with a posterior staphyloma, may be passed if the ametropia do not exceed 2·5 D., and the candidate has a visual acuteness equal to that stated above.

Indian Medical Service

The candidate must have a visual acuteness of $\frac{6}{6}$ in one eye and $\frac{6}{12}$ in the other. Hypermetropia and

myopia must not exceed 5 D., and then with the proper correction must come up to the above standard.

Astigmatism does not disqualify a candidate, provided the combined spherical and cylindrical glass does not exceed 5 D., and the visual acuteness equals $\frac{6}{6}$ in one eye and $\frac{6}{12}$ in the other. Colour-blindness, ocular paralysis, or any active disease of the fundus, renders the candidate ineligible.

Public Works

Candidates for the Departments of Public Works, Survey, Forest, Telegraph, Railways, Factories, and Police of India must pass the following eyesight tests. If myopic, the defect must not exceed 2·5 D., and with this glass the candidate may read $\frac{6}{9}$ in one eye and $\frac{6}{6}$ in the other. If myopic astigmatism is present, the vision must reach the above standard with correcting glasses, and the combined spherical and cylindrical glass must not exceed 2·5 D.

In hypermetropia and hypermetropic astigmatism an error of 4 D. is permissible provided that with this glass $\frac{6}{9}$ is read with one eye, and $\frac{6}{6}$ with the other.

Any disease of the eye may disqualify.

English Railways

There is, unfortunately, no uniform standard for our railways; each company has its own standard, in many cases a very low one: every engine driver should have at least $\frac{6}{12}$ in each eye without glasses, and normal colour vision.

TEST TYPES

No. 1. 25cm.*

it was much less easy to answer the chiefs of the opposition when they set forth the danger of breaking down the partition which separates the functions of the legislator from those of the judge. "This man," it was said, "may be a bad Englishman; and yet his cause may be the cause of all good Englishmen. Only last year we passed an Act to regulate the procedure of the ordinary courts in cases of treason. We passed that Act because we thought that, in those courts, the life of a subject obnoxious to the government was not then sufficiently secured. Yet the life of a subject obnoxious to the government was then far more secure than it will be if this House takes

No. 2. 33cm.

on itself to be the supreme criminal judicature in political cases." Warm eulogies were pronounced on the ancient national mode of trial by twelve good men and true; and indeed the advantages of that mode of trial in political cases are obvious. The prisoner is allowed to challenge any number of jurors with cause, and a considerable number without cause. The twelve, from the moment at which they are invested with their short magistracy, till the moment when they lay it down, are kept separate from the rest of the community. Every precaution is taken to prevent any agent of power from soliciting or corrupting them. Every one of them

No. 3. 50cm.

must hear every word of the evidence and every argument used on either side. The case is then summed up by a judge who knows that, if he is guilty of partiality, he may be called to account by the great inquest of the nation. In the trial of Fenwick at the bar of the House of Commons all these securities were wanting. Some hundreds of gentlemen, every one of whom had much more than half made up his mind before the case was opened, performed the functions both of judge and jury. They were not restrained, as a judge is restrained,

* The number indicates the distance at which the type should be seen by a normal eye.

No. 4. 75cm.

by the sense of responsibility; for who was to punish a Parliament? They were not selected, as a jury is selected, in a manner which enables the culprit to exclude his personal and political enemies. The arbiters of his fate came in and went out as they chose They heard a fragment here and there of what was said against him,

No. 5. 1m.

and a fragment here and there of what was said in his favour. During the progress of the bill they were exposed to every species of influence. One member was threatened by the electors of his borough with the loss of his seat: another might obtain a frigate for his brother from

☞ *The prices as given in this Catalogue are net. Cloth binding, unless otherwise specified. Postpaid, upon receipt of advertised price.*

SPECIAL NOTE.—The prices given in this catalogue are absolutely net, no discount will be allowed retail purchasers under any consideration. This rule has been established in order that everyone will be treated alike, a general reduction in former prices having been made to meet previous retail discounts. Upon receipt of the advertised price any book will be forwarded by mail or express, **all charges prepaid.**

ANATOMY.

MORRIS. Text-Book of Anatomy. 2d Edition. Revised and Enlarged. 790 Illustrations, 214 of which are printed in colors. *Just Ready.* Cloth, $6.00; Leather, $7.00; Half Russia, $8.00

"Taken as a whole, we have no hesitation in according very high praise to this work. It will rank, we believe, with the leading Anatomies. The illustrations are handsome and the printing is good."—*Boston Medical and Surgical Journal.*

Sample pages and illustrations will be sent free to any address.

BROOMELL. Anatomy and Histology of the Human Mouth and Teeth. 284 Illustrations. $4 50

DEAVER. Surgical Anatomy. A Treatise on Human Anatomy in its Application to Medicine and Surgery. With about 400 very Handsome full-page Illustrations Engraved from Original Drawings made by special Artists from dissections prepared for the purpose. Three Volumes. Royal Square Octavo.

Cloth, $21 00; Half Morocco or Sheep, $24.00; Half Russia, $27.00

ECKLEY. Practical Anatomy. A Manual for the use of Students in the Dissecting Room. Based upon Morris' Text-Book of Anatomy and Including a Section on the Fundamental Principles of Anatomy. With 347 Illustrations, many of which are in colors.

Cloth, $3 50; Oil Cloth, $4.00

GORDINIER. Anatomy of the Central Nervous System. With 271 Illustrations, many of which are original.

Cloth, $6.00; Sheep, $7.00

HEATH. Practical Anatomy. 8th Edition. 300 Illus. $4.25

HOLDEN. Anatomy. A Manual of the Dissections of the Human Body. Carefully Revised by A. HEWSON, M.D., Demonstrator of Anatomy, Jefferson Medical College, Philadelphia. 300 Illustrations. 7th Edition. *In Press.*

HOLDEN. Human Osteology. Comprising a Description of the Bones, with Colored Delineations of the Attachments of the Muscles. The General and Microscopical Structure of Bone and its Development. With Lithographic Plates and numerous Illus. 8th Ed. $5.25

HOLDEN. Landmarks. Medical and Surgical. 4th Ed. $1 00

MACALISTER. Human Anatomy. Systematic and Topographical, including the Embryology, Histology, and Morphology of Man. With Special Reference to the Requirements of Practical Surgery and Medicine. 816 Illustrations. Cloth, $5.00; Leather, $6.00

MARSHALL. Physiological Diagrams. Life Size, Colored. Eleven Life-Size Diagrams (each seven feet by three feet seven inches). Designed for Demonstration before the Class.

In Sheets, Unmounted, $40.00; Backed with Muslin and Mounted on Rollers, $60.00; Ditto, Spring Rollers, in Handsome Walnut Wall Map Case, $100.00; Single Plates—Sheets, $5.00; Mounted, $7.50. Explanatory Key, .50. *Purchaser must pay freight charges.*

POTTER. Compend of Anatomy, Including Visceral Anatomy. 6th Ed. 16 Lith. Plates and 117 other Illus. .80; Interleaved, $1.25

WILSON. Human Anatomy. 11th Edition. 429 Illustrations, 26 Colored Plates, and a Glossary of Terms. $5.00

WINDLE. Surface Anatomy. Colored and other Illus. $1.00

BRAIN AND INSANITY (see also Nervous Diseases).

BLACKBURN. A Manual of Autopsies. Designed for the Use of Hospitals for the Insane and other Public Institutions. Ten full-page Plates and other Illustrations. $1.25

GORDINIER. The Gross and Minute Anatomy of the Central Nervous System. With many full-page and other Illustrations. 8vo. Cloth, $6.00; Sheep, $7.00

GOWERS. Diagnosis of Diseases of the Brain. 2d Edition. Illustrated. $1.50

HORSLEY. The Brain and Spinal Cord. The Structure and Functions of. Numerous Illustrations. $2.50

LEWIS (BEVAN). Mental Diseases A Text Book Having Special Reference to the Pathological Aspects of Insanity. 26 Lithographic Plates and other Illustrations. 2d Ed. *Just Ready.* $7.00

MANN. Manual of Psychological Medicine and Allied Nervous Diseases. Their Diagnosis, Pathology, Prognosis, and Treatment, including their Medico-Legal Aspects. Illus. $3.00

REGIS. Mental Medicine. Authorized Translation by H. M. BANNISTER, M.D. $2.00

SHUTTLEWORTH. Mentally Deficient Children. New Edition. *In Press.*

STEARNS. Mental Diseases. With a Digest of Laws of the various States Relating to Care of Insane. Illustrated. Cloth, $2.75; Sheep, $3.25

TUKE. Dictionary of Psychological Medicine. Giving the Definition, Etymology, and Symptoms of the Terms used in Medical Psychology, with the Symptoms, Pathology, and Treatment of the Recognized Forms of Mental Disorders, together with the Law of Lunacy in Great Britain and Ireland. Two volumes. $10.00

WOOD, H. C. Brain and Overwork. .40

CHEMISTRY AND TECHNOLOGY.

Special Catalogue of Chemical Books sent free upon application.

ALLEN. Commercial Organic Analysis. A Treatise on the Modes of Assaying the Various Organic Chemicals and Products Employed in the Arts, Manufactures, Medicine, etc., with concise methods for the Detection of Impurities, Adulterations, etc. 8vo.

Vol. I. Alcohols, Neutral Alcoholic Derivatives, etc., Ethers, Vegetable Acids, Starch, Sugars, etc. 3d Edition, by HENRY LEFFMANN, M. D. 1898. $4.50

Vol. II, Part I. Fixed Oils and Fats, Glycerol, Explosives, etc. 3d Edition, by HENRY LEFFMANN, M. D. 1899. $3.50

Vol. II, Part II. Hydrocarbons, Mineral Oils, Phenols, etc. 3d Edition, by HENRY LEFFMANN, M.D. *Nearly Ready.*

Vol. III, Part I. Acid Derivatives of Phenols, Aromatic Acids, Tannins, Dyes and Coloring Matters. 3d Edition. Revised by J. MERRITT MATHEWS, PH.D., of the Philadelphia Textile School. Illustrated. *In Press.*

Vol. III, Part II. The Amines, Hydrazines and Derivatives, Pyridine Bases. The Antipyretics, etc. Vegetable Alkaloids, Tea, Coffee, Cocoa, etc. 8vo. 2d Edition. 1892. $4 50

Vol. III, Part III. Vegetable Alkaloids, Non-Basic Vegetable Bitter Principles. Animal Bases, Animal Acids, Cyanogen Compounds, etc. 2d Edition, 8vo. 1896. $4.50

Vol. IV. The Proteids and Albuminous Principles. 2d Edition. 1898. $4.50

ALLEN. Albuminous and Diabetic Urine. Illustrated. $2.25

BARTLEY. Medical and Pharmaceutical Chemistry. A Text-Book for Medical, Dental, and Pharmaceutical Students. With Illustrations, Glossary, and Complete Index. 5th Edition, carefully Revised. Cloth, $3.00; Sheep, $3.50

BARTLEY. Clinical Chemistry. The Examination of Feces, Saliva, Gastric Juice, Milk, and Urine. $1.00

BLOXAM. Chemistry, Inorganic and Organic. With Experiments. 8th Ed., Revised 281 Engravings. Clo., $4.25; Lea., $5.25

CALDWELL. Elements of Qualitative and Quantitative Chemical Analysis. 3d Edition, Revised. $1.50

CAMERON. Oils and Varnishes. With Illustrations. $2.25

CAMERON. Soap and Candles. 54 Illustrations. $2.00

GARDNER. The Brewer, Distiller, and Wine Manufacturer. Illustrated. $1.50

GARDNER. Bleaching, Dyeing, and Calico Printing. $1.50

GROVES AND THORP. Chemical Technology. The Application of Chemistry to the Arts and Manufactures.
Vol. I. Fuel and Its Applications. 607 Illustrations and 4 Plates. Cloth, $5.00; Half Morocco, $6.50
Vol. II. Lighting. Illustrated. Cloth, $4.00; Half Morocco, $5.50
Vol. III. Lighting—Continued. *In Press.*
Vol. IV. Electric Lighting. *In Press.*

HOLLAND. The Urine, the Gastric Contents, the Common Poisons, and the Milk. Memoranda, Chemical and Microscopical, for Laboratory Use. 6th Ed. Illustrated and interleaved, $1.00

LEFFMANN. Compend of Medical Chemistry, Inorganic and Organic. Including Urine Analysis. 4th Edition, Rewritten and Revised. .80; Interleaved, $1.25

LEFFMANN. Analysis of Milk and Milk Products. Arranged to Suit the Needs of Analytical Chemists, Dairymen, and Milk Inspectors. 2d Edition. Enlarged, Illustrated. $1.25

LEFFMANN. Water Analysis. For Sanitary and Technic Purposes. Illustrated. 4th Edition. *Just Ready.* $1.25

LEFFMANN. Structural Formulæ. Including 180 Structural and Stereo-Chemical Formulæ. 12mo. Interleaved. $1.00

MUTER. Practical and Analytical Chemistry. 2d American from the Eighth English Edition. Revised to meet the requirements of American Students. 56 Illustrations. $1.25

OETTEL. Exercises in Electro-Chemistry. Illustrated. .75

OETTEL. Electro-Chemical Experiments. Illustrated. .75

RICHTER. Inorganic Chemistry. 4th American, from 6th German Edition. Authorized translation by EDGAR F. SMITH, M.A., PH.D. 89 Illustrations and a Colored Plate. $1.75

RICHTER. Organic Chemistry. 3d American Edition. Trans. from the 8th German by EDGAR F. SMITH. Illustrated. 2 Volumes.
Vol. I. Aliphatic Series. 625 Pages. $3.00
Vol. II. Carbocyclic Series. 671 Pages. $3.00

SMITH. Electro-Chemical Analysis. 2d Edition, Revised. 28 Illustrations. $1.25

SMITH AND KELLER. Experiments. Arranged for Students in General Chemistry. 3d Edition. Illustrated. .60

SUTTON. Volumetric Analysis. A Systematic Handbook for the Quantitative Estimation of Chemical Substances by Measure, Applied to Liquids, Solids, and Gases. 8th Edition, Revised 112 Illustrations. *In Press.*

SYMONDS. Manual of Chemistry, for Medical Students. 2d Edition. $2.00

TRAUBE. Physico-Chemical Methods. Translated by Hardin. 97 Illustrations. $1.50

THRESH. Water and Water Supplies. 2d Edition. $2.00

ULZER AND FRAENKEL. Chemical Technical Analysis. Translated by Fleck. Illustrated. $1.25

WOODY. Essentials of Chemistry and Urinalysis. 4th Edition. Illustrated. *In Press.*

*** *Special Catalogue of Books on Chemistry free upon application.*

CHILDREN.

CAUTLIE. Feeding of Infants and Young Children by Natural and Artificial Methods. $2.00

HALE. On the Management of Children. .50

HATFIELD. Compend of Diseases of Children. With a Colored Plate. 2d Edition. .80; Interleaved, $1.25

MEIGS. Infant Feeding and Milk Analysis. The Examination of Human and Cow's Milk, Cream, Condensed Milk, etc., and Directions as to the Diet of Young Infants. .50

POWER. Surgical Diseases of Children and their Treatment by Modern Methods. Illustrated. $2.50

SHUTTLEWORTH. Mentally Deficient Children. New Edition. *In Press.*

STARR. The Digestive Organs in Childhood. The Diseases of the Digestive Organs in Infancy and Childhood. With Chapters on the Investigation of Disease and the Management of Children. 2d Edition, Enlarged. Illustrated by two Colored Plates and numerous Wood Engravings. $2.00

STARR. Hygiene of the Nursery. Including the General Regimen and Feeding of Infants and Children, and the Domestic Management of the Ordinary Emergencies of Early Life, Massage, etc. 6th Edition. 25 Illustrations. $1.00

SMITH. Wasting Diseases of Children. 6th Edition. $2.00

TAYLOR AND WELLS. The Diseases of Children. Illustrated. A New Manual. 746 pages. $4.00

CLINICAL CHARTS.

GRIFFITH. Graphic Clinical Chart for Recording Temperature, Respiration, Pulse, Day of Disease, Date, Age, Sex, Occupation, Name, etc. Printed in three colors. Sample copies free. Put up in loose packages of fifty, .50. Price to Hospitals, 500 copies, $4.00; 1000 copies, $7.50. With name of Hospital printed on, .50 extra.

KEEN'S CLINICAL CHARTS. Seven Outline Drawings of the Body, on which may be marked the Course of Disease, Fractures, Operations, etc. Pads of fifty, $1.00. Each Drawing may also be had separately, twenty-five to pad, 25 cents.

SCHREINER. Diet Lists. Arranged in the form of a chart. With Pamphlets of Specimen Dietaries. Pads of 50. .75

DENTISTRY.

Special Catalogue of Dental Books sent free upon application.

BARRETT. Dental Surgery for General Practitioners and Students of Medicine and Dentistry. Extraction of Teeth, etc. 3d Edition. Illustrated. *Nearly Ready.*

BROOMELL. Anatomy and Histology of the Human Mouth and Teeth. 284 Handsome Illustrations. $4.50

FLAGG. Plastics and Plastic Filling, as Pertaining to the Filling of Cavities in Teeth of all Grades of Structure. 4th Edition. $4.00

FILLEBROWN. A Text-Book of Operative Dentistry. Written by invitation of the National Association of Dental Faculties. Illustrated. $2.25

GORGAS. Dental Medicine. A Manual of Materia Medica and Therapeutics. 6th Edition, Revised. Cloth, $4.00; Sheep, $5.00

HARRIS. Principles and Practice of Dentistry. Including Anatomy, Physiology, Pathology, Therapeutics, Dental Surgery, and Mechanism. 13th Edition. Revised by F. J. S. GORGAS, M.D., D.D.S. 1250 Illustrations. Cloth, $6.00; Leather, $7.00

HARRIS. Dictionary of Dentistry. Including Definitions of Such Words and Phrases of the Collateral Sciences as Pertain to the Art and Practice of Dentistry. 6th Edition. Revised and Enlarged by FERDINAND F. S. GORGAS, M.D., D.D.S. Cloth, $5.00; Leather, $6.00

HEATH. Injuries and Diseases of the Jaws. 4th Edition. 187 Illustrations. $4.50

HEATH. Lectures on Certain Diseases of the Jaws. 64 Illustrations. Boards, .50

RICHARDSON. Mechanical Dentistry. 7th Edition. Thoroughly Revised and Enlarged by DR. GEO. W. WARREN. 691 Illustrations. Cloth, $5.00; Leather, $6.00

SEWELL. Dental Surgery. Including Special Anatomy and Surgery. 3d Edition, with 200 Illustrations. $2.00

SMITH. Dental Metallurgy. Illustrated. $1.75

TAFT. Index of Dental Periodical Literature. $2.00

TALBOT. Irregularities of the Teeth and Their Treatment. 2d Edition. 234 Illustrations. $3.00

TOMES. Dental Anatomy. Human and Comparative. 263 Illustrations. 5th Edition. $4.00

TOMES. Dental Surgery. 4th Edition. 289 Illustrations. $4.00

WARREN. Compend of Dental Pathology and Dental Medicine. With a Chapter on Emergencies. 3d Edition. Illustrated. .80; Interleaved, $1.25

WARREN. Dental Prosthesis and Metallurgy. 129 Ills. $1.25

WHITE. The Mouth and Teeth. Illustrated. .40

*** *Special Catalogue of Dental Books free upon application.*

DICTIONARIES.

GOULD. The Illustrated Dictionary of Medicine, Biology, and Allied Sciences. Being an Exhaustive Lexicon of Medicine and those Sciences Collateral to it: Biology (Zoology and Botany), Chemistry, Dentistry, Parmacology, Microscopy, etc., with many useful Tables and numerous fine Illustrations. 1633 pages. 4th Ed.
Sheep or Half Dark Green Leather, $10.00; Thumb Index, $11.00
Half Russia, Thumb Index, $12.00

GOULD. The Medical Student's Dictionary. Including all the Words and Phrases Generally Used in Medicine, with their Proper Pronunciation and Definition, Based on Recent Medical Literature. With Tables of the Bacilli, Micrococci, Mineral Springs, etc., of the Arteries, Muscles, Nerves, Ganglia, and Plexuses, etc. **10th Edition. Rewritten and Enlarged.** Completely reset from new type. 700 pp.
Half Dark Leather, $3.25; Half Morocco, Thumb Index, $4.00

GOULD. The Pocket Pronouncing Medical Lexicon. 4th Edition. (30,000 Medical Words Pronounced and Defined.) Containing all the Words, their Definition and Pronunciation, that the Medical, Dental, or Pharmaceutical Student Generally Comes in Contact With; also Elaborate Tables of the Arteries, Muscles, Nerves, Bacilli, etc., etc., a Dose List in both English and Metric Systems, etc., Arranged in a Most Convenient Form for Reference and Memorizing. **A new Edition, Revised and Enlarged.** 838 pages. *Just Ready.*
Full Limp Leather, Gilt Edges, $1.00; Thumb Index, $1.25

100,000 Copies of Gould's Dictionaries Have Been Sold.

*** Sample Pages and Illustrations and Descriptive Circulars of Gould's Dictionaries sent free upon application.

HARRIS. Dictionary of Dentistry. Including Definitions of Such Words and Phrases of the Collateral Sciences as Pertain to the Art and Practice of Dentistry. 6th Edition. Revised and Enlarged by FERDINAND J. S. GORGAS, M.D., D.D.S. Cloth, $5.00; Leather, $6.00

LONGLEY. Pocket Medical Dictionary. With an Appendix, containing Poisons and their Antidotes, Abbreviations used in Prescriptions, etc. Cloth, .75; Tucks and Pocket, $1.00

MAXWELL. Terminologia Medica Polyglotta. By Dr. THEODORE MAXWELL, Assisted by Others. $3.00
The object of this work is to assist the medical men of any nationality in reading medical literature written in a language not their own. Each term is usually given in seven languages, viz.: English, French, German, Italian, Spanish, Russian, and Latin.

TREVES AND LANG. German-English Medical Dictionary.
Half Russia, $3.25

EAR (see also Throat and Nose).

BURNETT. Hearing and How to Keep It. Illustrated. .40

DALBY. Diseases and Injuries of the Ear. 4th Edition. 38 Wood Engravings and 8 Colored Plates. $2.50

HOVELL. Diseases of the Ear and Naso-Pharynx. Including Anatomy and Physiology of the Organ, together with the Treatment of the Affections of the Nose and Pharynx which Conduce to Aural Disease. 122 Illustrations. 2d Edition. *Preparing.*

PRITCHARD. Diseases of the Ear. 3d Edition, Enlarged. Many Illustrations and Formulæ. $1.50

WOAKES. Deafness, Giddiness, and Noises in the Head. 4th Edition. Illustrated. $2.00

ELECTRICITY.

BIGELOW. Plain Talks on Medical Electricity and Batteries. With a Therapeutic Index and a Glossary. 43 Illustrations. 2d Edition. $1.00

HEDLEY. Therapeutic Electricity and Practical Muscle Testing. 99 Illustrations. *Just Ready.* $2.50

JONES. Medical Electricity. 3d Edition. 112 Illus. *In Press.*

MASON. Medical Electricity. Numerous Illustrations. .75

EYE.

A Special Circular of Books on the Eye sent free upon application.

DONDERS. The Nature and Consequences of Anomalies of Refraction. With Portrait and other Illustrations. 8vo. Half Morocco, $1.25

FICK. Diseases of the Eye and Ophthalmoscopy. Translated by A. B. HALE, M. D. 157 Illustrations, many of which are in colors, and a glossary. Cloth, $4.50; Sheep, $5.50

GOULD AND PYLE. Compend of Diseases of the Eye and Refraction. Including Treatment and Operations, and a Section on Local Therapeutics. With Formulæ, Useful Tables, a Glossary, and 111 Illus., several of which are in colors. 2d Edition, Revised. *Just Ready.* Cloth, 80; Interleaved, $1.25

GOWERS. Medical Ophthalmoscopy. A Manual and Atlas with Colored Autotype and Lithographic Plates and Wood-cuts, Comprising Original Illustrations of the Changes of the Eye in Diseases of the Brain, Kidney, etc. 3d Edition. $4.00

HARLAN. Eyesight, and How to Care for It. Illus. .40

HARTRIDGE. Refraction. 104 Illustrations and Test Types. 9th Edition, Enlarged. $1.50

HARTRIDGE. On the Ophthalmoscope. 3d Edition. With 4 Colored Plates and 68 Wood-cuts. $1.50

HANSELL AND REBER. Muscular Anomalies of the Eye. Illustrated. $1.50

HANSELL AND BELL. Clinical Ophthalmology. Colored Plate of Normal Fundus and 120 Illustrations. $1.50

JESSOP. Manual of Ophthalmic Surgery and Medicine. Colored Plates and 108 other Illustrations. Cloth, $3 00

MORTON. Refraction of the Eye. Its Diagnosis and the Correction of its Errors. 6th Edition. $1.00

OHLEMANN. Ocular Therapeutics. Authorized Translation, and Edited by DR. CHARLES A. OLIVER. $1.75

PHILLIPS. Spectacles and Eyeglasses. Their Prescription and Adjustment. 2d Edition. 49 Illustrations. $1.00

SWANZY. Diseases of the Eye and Their Treatment. 6th Edition, Revised and Enlarged. 158 Illustrations, 1 Plain Plate, and a Zephyr Test Card. $3.00

THORINGTON. Retinoscopy. 3d Edition. Illustrated. $1.00

THORINGTON. Refraction and How to Refract. 200 Illustrations, 13 of which are Colored. 301 pages. *Just Ready.* $1.50

WALKER. Students' Aid in Ophthalmology. Colored Plate and 40 other Illustrations and Glossary. $1.50

FEVERS.

COLLIE. On Fevers. Their History, Etiology, Diagnosis, Prognosis, and Treatment. Colored Plates. $2.00

GOODALL AND WASHBOURN. Fevers and Their Treatment. Illustrated. $3.00

GOUT AND RHEUMATISM.

DUCKWORTH. A Treatise on Gout. With Chromo-lithographs and Engravings. Cloth, $6.00

GARROD. On Rheumatism. A Treatise on Rheumatism and Rheumatic Arthritis. Cloth, $5.00

HAIG. Causation of Disease by Uric Acid. A Contribution to the Pathology of High Arterial Tension, Headache, Epilepsy, Gout, Rheumatism, Diabetes, Bright's Disease, etc. 4th Edition. $3.00

HEALTH AND DOMESTIC MEDICINE (see also Hygiene and Nursing).

BUCKLEY. The Skin in Health and Disease. Illus. .40

BURNETT. Hearing and How to Keep It. Illustrated. .40

COHEN. The Throat and Voice. Illustrated. .40

DULLES. Emergencies. 4th Edition. Illustrated. $1.00

HARLAN. Eyesight and How to Care for It. Illustrated. .40

HARTSHORNE. Our Homes. Illustrated. .40

OSGOOD. The Winter and its Dangers. .40

PACKARD. Sea Air and Bathing. .40

PARKES. The Elements of Health. $1.25

RICHARDSON. Long Life and How to Reach It. .40

WESTLAND. The Wife and Mother. $1.50

WHITE. The Mouth and Teeth. Illustrated. .40

WILSON. The Summer and its Diseases. .40

WOOD. Brain Work and Overwork. .40

STARR. Hygiene of the Nursery. 5th Edition. $1.00

CANFIELD. Hygiene of the Sick-Room. $1.25

HEART.

SANSOM. Diseases of the Heart. The Diagnosis and Pathology of Diseases of the Heart and Thoracic Aorta. With Plates and other Illustrations. $6.00

THORNE. The Schott Methods of the Treatment of Chronic Heart Disease. Third Edition. Illustrated. *Just Ready.* $1.75

HISTOLOGY.

STIRLING. Outlines of Practical Histology. 368 Illustrations. 2d Edition, Revised and Enlarged. With new Illustrations. $2.00

STÖHR. Histology and Microscopical Anatomy. Translated and Edited by A. SCHAPER, M.D., Harvard Medical School. Second American from 7th German Edition, Revised and Enlarged. 292 Illustrations. $3.00

HYGIENE AND WATER ANALYSIS.

Special Catalogue of Books on Hygiene sent free upon application.

CANFIELD. Hygiene of the Sick-Room. A Book for Nurses and Others. Being a Brief Consideration of Asepsis, Antisepsis, Disinfection, Bacteriology, Immunity, Heating, Ventilation, etc. $1.25

COPLIN AND BEVAN. Practical Hygiene. A Complete American Text-Book. 138 Illustrations. New Ed. *Preparing.*

KENWOOD. Public Health Laboratory Work. 116 Illustrations and 3 Plates. $2.00

LEFFMANN. Examination of Water for Sanitary and Technical Purposes. 4th Edition. Illustrated. *Just Ready* $1.25

LEFFMANN. Analysis of Milk and Milk Products. Illustrated. Second Edition. $1.25

LINCOLN. School and Industrial Hygiene. .40

MACDONALD. Microscopical Examinations of Water and Air. 25 Lithographic Plates, Reference Tables, etc. 2d Ed. $2.50

McNEILL. The Prevention of Epidemics and the Construction and Management of Isolation Hospitals. Numerous Plans and Illustrations. $3.50

NOTTER AND FIRTH. The Theory and Practice of Hygiene. (Being the 9th Edition of Parkes' Practical Hygiene, rewritten and brought up to date.) 10 Plates and 135 other Illustrations. 1034 pages. 8vo. $7.00

PARKES. Hygiene and Public Health. By Louis C. Parkes, M.D. 5th Edition. Enlarged. Illustrated. $2.50

PARKES. Popular Hygiene. The Elements of Health. A Book for Lay Readers. Illustrated. $1.25

STARR. The Hygiene of the Nursery. Including the General Regimen and Feeding of Infants and Children, and the Domestic Management of the Ordinary Emergencies of Early Life, Massage, etc. 6th Edition. 25 Illustrations. $1.00

STEVENSON AND MURPHY. A Treatise on Hygiene. By Various Authors. In Three Octave Volumes. Illustrated. Vol. I, $6.00; Vol. II, $6.00; Vol. III, $5.00

*** Each Volume sold separately. Special Circular upon application.

THRESH. Water and Water Supplies. 2d Edition. $2.00

WILSON. Hand-Book of Hygiene and Sanitary Science. With Illustrations. 8th Edition. $3.00

WEYL. Sanitary Relations of the Coal-Tar Colors. Authorized Translation by HENRY LEFFMANN, M.D., PH.D. $1.25

LUNGS AND PLEURÆ.

HARRIS AND BEALE. Treatment of Pulmonary Consumption. $2.50

KNOPF. Pulmonary Tuberculosis. Its Modern Prophylaxis and Treatment in Special Institutions and at Home. Illus. $3.00

POWELL. Diseases of the Lungs and Pleuræ, including Consumption. Colored Plates and other Illus. 4th Ed. $4.00

TUSSEY. High Altitudes in the Treatment of Consumption. $1.50

MASSAGE.

KLEEN. Hand-Book of Massage. Authorized translation by MUSSEY HARTWELL, M.D., PH.D. With an Introduction by Dr. S. WEIR MITCHELL. Illustrated by a series of Photographs Made Especially by DR. KLEEN for the American Edition. $2.25

OSTROM. Massage and the Original Swedish Movements. Their Application to Various Diseases of the Body. A Manual for Students, Nurses, and Physicians. Fourth Edition, Enlarged. 105 Illustrations, many of which are original. $1.00

WARD. Notes on Massage. Interleaved. Paper cover, $1.00

MATERIA MEDICA AND THERAPEUTICS.

ALLEN, HARLAN, HARTE, VAN HARLINGEN. A Hand-Book of Local Therapeutics, Being a Practical Description of all those Agents Used in the Local Treatment of Diseases of the Eye, Ear, Nose and Throat, Mouth, Skin, Vagina, Rectum, etc., such as Ointments, Plasters, Powders, Lotions, Inhalations, Suppositories, Bougies, Tampons, and the Proper Methods of Preparing and Applying Them. Cloth, $3.00; Sheep, $4.00

BIDDLE. Materia Medica and Therapeutics. Including Dose List, Dietary for the Sick, Table of Parasites, and Memoranda of New Remedies. 13th Edition, Thoroughly Revised in accordance with the new U. S. P. 64 Illustrations and a Clinical Index. Cloth, $4.00; Sheep, $5.00

In preparing, revising, and improving Blakiston's ? Quiz-Compends ? the particular wants of the student have always been kept in mind.

Careful attention has been given to the construction of each sentence, and while the books will be found to contain an immense amount of knowledge in small space, they will likewise be found easy reading; there is no stilted repetition of words; the style is clear, lucid, and distinct. The arrangement of subjects is systematic and thorough; there is a reason for every word. They contain over 600 illustrations.

Morris' Anatomy

Second Edition,
Revised and Enlarged.

790 Illustrations, of which many are in Colors.

Royal Octavo. Cloth, $6.00; Sheep, $7.00; Half Russia, $8.00.

From The Medical Record, New York.

"The reproach that the English language can boast of no treatise on anatomy deserving to be ranked with the masterly works of Henle, Luschka, Hyrtl, and others, is fast losing its force. During the past few years several works of great merit have appeared, and among these Morris's "Anatomy" seems destined to take first place in disputing the palm in anatomical fields with the German classics. The nomenclature, arrangement, and entire general character resemble strongly those of the above-mentioned handbooks, while in the beauty and profuseness of its illustrations it surpasses them. . . . The ever-growing popularity of the book with teachers and students is an index of its value, and it may safely be recommended to all interested."

***** Handsome Descriptive Circular, with Sample Pages and Colored Illustrations, will be sent free upon application.**
